Several different types of source have been employed for the excitation of characteristic X-radiation, including those based on electrons, X-rays, γ rays, protons, and synchrotron radiation. Sometimes a bremsstrahlung X-ray source is used to generate specific X-radiation from an intermediate pure element sample, called a secondary fluorescer. By far the most common source today is the X-ray photon source. This source is used in primary mode in the wavelength and primary energy dispersive systems, and in secondary fluorescer mode in secondary target energy dispersive spectrometers. A γ-source is typically a radioisotope that is used either directly, or in a mode equivalent to the secondary fluorescer mode in energy dispersive spectrometry. Most conventional wavelength dispersive X-ray spectrometers use a high-power (2 – 4 kW) X-ray bremsstrahlung source. Energy dispersive spectrometers use either a high- or low-power (0.5 – 1.0 kW) primary source, depending on whether the spectrometer is used in the secondary or primary mode. In all cases, the primary source unit consists of a very stable high-voltage generator, capable of providing a potential of typically 40 – 100 kV. The current from the generator is fed to the filament of the X-ray tube, which is typically a coil of tungsten wire. The applied current causes the filament to glow and emit electrons. A portion of this electron cloud is accelerated to the anode of the X-ray tube, which is typically a water-cooled block of copper with the required anode material plated or cemented to its surface. The impinging electrons produce X-radiation, a significant portion of which passes through a thin beryllium window to the specimen.

4.2. Detectors

An X-ray detector is a transducer for converting X-ray photon energy into voltage pulses. Detectors work by a process of photoionization, in which interaction between the incoming X-ray photon and the active detector material produces a number of electrons. The current produced by these electrons is converted to a voltage pulse by a capacitor and resistor, such that one digital voltage pulse is produced for each entering X-ray photon. In addition to being sensitive to the appropriate photon energies, i.e., being applicable to a given range of wavelengths or energies, there are two other important properties that an ideal detector should possess: proportionality and linearity. Each X-ray photon entering the detector produces a voltage pulse, and if the size of the voltage pulse is proportional to the photon energy, the detector is said to be proportional. Proportionality is needed where the technique of pulse height selection is to be used. Pulse height selection is a means of electronically rejecting pulses of voltage levels other than those corresponding to the characteristic line being measured. X-ray photons enter the detector at a certain rate and, if the output pulses are produced at the same rate, the detector is said to be linear. Linearity is important where the various count rates produced by the detector are to be used as measures of the photon intensity for each measured line.

In the case of wavelength dispersive spectrometers, the gas flow proportional counter is generally employed for the measurement of longer wavelengths, and the scintillation counter for shorter wavelengths. Neither of these detectors has sufficient resolution to separate multiple wavelengths on its own, and so they have to be employed along with an analyzing crystal. However, in the case of energy dispersive spectrometry, where no dispersing crystal is employed, a detector of higher resolution must be used, generally the Si(Li) detector.

The Si(Li) detector consists of a small cylinder (ca. 1 cm diameter and 3 mm thick) of *p*-type silicon, compensated by lithium to increase its electrical resistivity. A Schottky barrier contact on the front of the silicon disk produces a *p-i-n*-type diode. To inhibit the mobility of the lithium ions and to reduce electronic noise, the diode and its preamplifier are cooled to liquid-nitrogen temperature. Incident X-ray photons interact to produce a specific number of

electron – hole pairs. The charge produced is swept from the diode by the bias voltage to a charge-sensitive preamplifier. A charge loop integrates the charge on a capacitor to produce an output pulse. Special energy dispersive detectors have been used in miniaturized instrumentation for in vivo applications [10] and for in situ analysis [11].

4.3. Types of Spectrometer

The basic function of the spectrometer is to separate the polychromatic beam of radiation coming from the specimen in order that the intensity of each individual characteristic line can be measured. A spectrometer should provide sufficient resolution of lines to allow such data to be taken, at the same time providing a sufficiently large response above background to make the measurements statistically significant, especially at low analyte concentrations. It is also necessary that the spectrometer allow measurements over the wavelength range to be covered. Thus, in the selection of a set of spectrometer operating variables, four factors are important: resolution, response, background level, and range. Owing to many factors, optimum selection of some of these characteristics may be mutually exclusive; as an example, attempts to improve resolution invariably cause lowering of absolute peak intensities. There is a wide variety of instrumentation available today for the application of X-ray fluorescence techniques and it is useful to break the instrument types down into three main categories: wavelength dispersive spectrometers (sequential and simultaneous); energy dispersive spectrometers (primary or secondary); and special spectrometers (including total reflection, synchrotron source, and proton-induced). The wavelength dispersive system was introduced commercially in the early 1950s and probably around 25 000 such instruments have been supplied commercially. Energy dispersive spectrometers became commercially available in the early 1970s and today there are around 15 000 of these units in use. There are far fewer of the specialized spectrometers in use and these generally incorporate an energy dispersive rather than a wavelength dispersive spectrometer.

X-ray spectrometers differ in the number of elements measurable at one time, and the speed at which they collect data. All of the instruments are, in principle at least, capable of measuring all elements from $Z = 9$ (fluorine) upwards, and most modern wavelength dispersive spectrometers can do useful measurements down to $Z = 6$ (carbon). Most systems can be equipped with multisample handling facilities and can be automated by use of minicomputers. Typical spectrometer systems are capable of precision on the order of a few tenths of a percent, with sensitivities down to the low ppm level. Single-channel wavelength dispersive spectrometers are typically employed for routine and nonroutine analysis of a wide range of products, including ferrous and nonferrous alloys, oils, slags and sinters, ores and minerals, thin films, etc. These systems are very flexible, but somewhat slower than multichannel spectrometers. Multichannel wavelength dispersive instruments are used almost exclusively for routine, high-throughput analyses where the great need is for fast, accurate analysis, but where flexibility is of no importance. Energy dispersive spectrometers have the great advantage of being able to display information on all elements at the same time. They lack somewhat in resolution compared with wavelength dispersive spectrometers, but the ability to reveal elements absent, as well as elements present, makes the energy dispersive spectrometer ideal for general trouble-shooting problems. They have been particularly effective in the fields of scrap alloy sorting, in forensic science, and in the provision of elemental data to supplement X-ray powder diffraction data.

4.4. Wavelength Dispersive Systems

A wavelength dispersive spectrometer may be a single-channel instrument in which a single crystal and a single detector are used for the sequential measurement of a series of wavelengths; or a multichannel spectrometer in which many crystal – detector sets are used to measure elements simultaneously. Of these two basic types, the sequential systems are the most common. A typical sequential spectrometer system consists of the X-ray tube, a specimen holder, a primary collimator, an analyzing crystal, and a detector. A portion of the characteristic fluorescence radiation from the specimen is passed via

a collimator or slit onto the surface of an analyzing crystal, where individual wavelengths are diffracted to the detector in accordance with the Bragg law. A goniometer is used to maintain the required $\theta - 2\theta$ relationship between crystal and detector. Typically, about six different analyzing crystals and two different collimators are provided in this type of spectrometer, giving the operator a wide choice of dispersion conditions. The separating power of a crystal spectrometer depends on the divergence allowed by the collimators, which to a first approximation determines the width of the diffracted lines, and the angular dispersion of the crystal [12]. While the maximum wavelength covered by traditional spectrometer designs is about 2 nm, more recent developments allow extension of the wavelength range significantly beyond this value.

The output from a wavelength dispersive spectrometer may be either analog (a) or digital (d). For qualitative work, an analog output is traditionally used; the digital output from the detector amplifier is fed through a d/a converter, called a rate meter, to an *x*/*t* recorder synchronously coupled with the goniometer scan speed. The recorder thus records an intensity – time diagram, in terms of an intensity – 2θ diagram. It is generally more convenient to employ digital counting for quantitative work, and a timer – scaler combination is provided which allows pulses to be integrated over a period of several tens of seconds and then displayed as count or count rate. In more modern spectrometers, a scaler – timer may take the place of the rate meter, using step-scanning. Some automated wavelength dispersive spectrometers provide the user with software programs for the interpretation and labeling of peaks [13].

4.5. Energy Dispersive Systems

The energy dispersive spectrometer consists of the excitation source and the spectrometer/detection system. The spectrometer/detector is typically a Si(Li) detector. A multichannel analyzer is used to collect, integrate, and display the resolved pulses. While similar properties are sought from the energy dispersive system as with the wavelength dispersive system, the means of selecting these optimum conditions are very different. Since the resolution of the energy dispersive system equates directly to the resolution of the detector, this feature is of paramount importance. The output from an energy dispersive spectrometer is generally displayed on a cathode ray tube, and the operator is able to dynamically display the contents of the various channels as an energy spectrum. Provision is generally made to allow zooming in on portions of the spectrum of special interest, to overlay spectra, to subtract background, etc. Generally, some form of minicomputer is available for spectral stripping, peak identification, quantitative analysis, and other useful functions.

All of the earlier energy dispersive spectrometers were operated in what is called the primary mode and consisted simply of the excitation source, typically a closely coupled low-power, end-window X-ray tube, and the detection system. In practice there is a limit to the maximum count rate that the spectrometer can handle and this led, in the mid-1970s, to the development of the secondary mode of operation. In the secondary mode, a carefully selected pure element standard is interposed between primary source and specimen, along with absorption filters, such that a selectable energy range of secondary photons is incident on the sample. This allows selective excitation of certain portions of the energy range, thus increasing the ratio of useful to unwanted photons entering the detector. While this configuration does not completely eliminate the count rate and resolution limitations of the primary system, it certainly does reduce them.

5. Accuracy

5.1. Counting Statistical Errors

The production of X-rays is a random process that can be described by a Gaussian distribution. Since the number of photons counted is nearly always large, typically thousands or hundreds of thousands, rather than a few hundred, the properties of the Gaussian distribution can be used to predict the probable error for a given count measurement. The random error $\sigma(N)$ associated with a measured value of N, is equal to $\sqrt{N}$. For example, if 10^6 counts are taken, the standard deviation σ is $\sqrt{10^6} = 10^3$, or 0.1 %. The measured parameter in wavelength dispersive X-ray spectrometry is generally the counting rate

R, and the magnitude of the random counting error associated with a given datum can be expressed as:

$$\sigma\,(\%) = 100/\sqrt{N} = 100/\sqrt{(Rt)} \tag{5}$$

Care must be exercised in relating the counting error (or indeed any intensity-related error) with an estimate of the error in terms of concentration. Provided that the sensitivity of the spectrometer in count rate (*c*/*s*) per percent analyte is linear, the count error can be directly related to a concentration error. However, where the sensitivity of the spectrometer changes over the range of measured response, a given fractional count error may be much greater when expressed in terms of concentration. In many analytical situations, the peak lies above a significant background and this adds a further complication to the counting statistical error.

5.2. Matrix Effects

In the conversion of net line intensity to analyte concentration, it may be necessary to correct for absorption and/or enhancement effects. Absorption effects include both primary and secondary absorption. Primary absorption occurs because all atoms of the specimen matrix absorb photons from the primary source. Since there is competition for these primary photons by the atoms making up the specimen, the intensity – wavelength distribution of the photons available for excitation of a given analyte element may be modified by other matrix elements. Secondary absorption refers to the absorption of characteristic analyte radiation by the specimen matrix. As characteristic radiation passes out from the specimen in which it was generated, it is absorbed by all matrix elements by amounts relative to their mass attenuation coefficients. The total absorption of a specimen depends on both primary and secondary absorption. Enhancement effects occur when a nonanalyte matrix element emits a characteristic line, of energy just in excess of the absorption edge of the analyte element. This means that the nonanalyte element is able to excite the analyte, giving characteristic photons in addition to those produced by the primary continuum. This gives an enhanced signal from the analyte.

6. Quantitative Analysis

The simplest quantitative analysis situation to handle is the determination of a single element in a known matrix. In this instance, a simple calibration curve of analyte concentration versus line intensity is sufficient for quantitative determination. A slightly more difficult case might be the determination of a single element where the matrix is unknown. Three basic methods are commonly employed in this situation: use of internal standards, addition of standards, and use of a scattered line from the X-ray source. The most complex case is the analysis of all, or most, of the elements in a sample, about which little or nothing is known. In this case a full qualitative analysis would be required before any attempt is made to quantitate the matrix elements. Once the qualitative composition of the sample is known, one of three general techniques is typically applied: type standardization, influence coefficient methods, or fundamental parameter techniques. Both the influence coefficient and fundamental parameter techniques require a computer for their application.

In principle, an empirical correction procedure can be described as the correction of an analyte element intensity for the influence of interfering elements, using the product of the intensity from the interfering element line and a constant factor, as the correction term [14]. This constant factor is today generally referred to as an influence coefficient, since it is assumed to represent the influence of the interfering element on the analyte. Commonly employed influence coefficient methods may use either the intensity or the concentration of the interfering element as the correction term. These methods are referred to as intensity correction and concentration correction methods, respectively. Intensity correction models give a series of linear equations which do not require much computation, but they are generally not applicable to wide ranges of analyte concentration. Various versions of the intensity correction models found initial application in the analysis of nonferrous metals where correction constants were applied as look-up tables. Later versions [15] were supplied on commercially available computer-controlled spectrometers, and were used for a wider range of application. A concentration model (e.g., [16])

requires the solving of a series of simultaneous equations by regression analysis or matrix inversion techniques. This approach is more rigorous than the intensity models, and so it became popular in the early 1970s as suitable low-cost minicomputers became available.

6.1. Internal Standards

One of the most useful techniques for the determination of a single analyte element in a known or unknown matrix is to use an internal standard. The technique is one of the oldest methods of quantitative analysis and is based on the addition of a known concentration of an element that gives a wavelength close to that of the analyte. The assumption is made that the effect of the matrix on the internal standard is essentially the same as the effect of the matrix on the analyte element. Internal standards are best suited to the measurement of analyte concentrations below about 10 %. Care must also be taken to ensure that the particle sizes of specimen and internal standard are about the same, and that the two components are adequately mixed. Where an appropriate internal standard cannot be found, it may be possible to use the analyte itself as an internal standard. This method is a special case of standard addition, and it is generally referred to as spiking.

6.2. Type Standardization

Provided that the total specimen absorption does not vary significantly over a range of analyte concentrations, and provided that enhancement effects are absent, and that the specimen is homogeneous, a linear relationship will be obtained between analyte concentration and measured characteristic line intensity. Where these provisos are met, type standardization techniques can be employed. Type standardization is probably the oldest of the quantitative analytical methods employed, and the method is usually evaluated by taking data from a well-characterized set of standards and, by inspection, establishing whether a linear relationship is indeed observed. Where this is not the case, the analyte concentration range may be further restricted. The analyst of today is fortunate in that many hundreds of good reference standards are commercially available. While the type standardization method is not without its pitfalls, it is nevertheless extremely useful, especially for quality control applications where a finished product is compared with a desired product.

6.3. Influence Correction Methods

Influence coefficient correction procedures can be divided into three basic types: fundamental, derived, and regression. Fundamental models are those which require starting with concentrations, then calculating the intensities. Derived models are based on some simplification of a fundamental method but still allow concentrations to be calculated from intensities. Regression models are semiempirical in nature and allow the determination of influence coefficients by regression analysis of data sets obtained from standards. All regression models have essentially the same form and consist of: a weight fraction term W (or concentration C); an intensity (or intensity ratio) term I; an instrument-dependent term which essentially defines the sensitivity of the spectrometer for the analyte in question; and a correction term, which corrects the instrument sensitivity for the effect of the matrix. The general form is:

$$W = I\,(\text{instrument})\,[1 + \{\text{model}\}] \tag{6}$$

Equation (6) shows that the weight fraction W of analyte is proportional to the product of the measured intensity I of the analyte, corrected for instrumental effects, and a matrix correction term. Different models vary only in the form of this correction term.

The major advantage of influence coefficient methods is that a wide range of concentration ranges can be covered by using a relatively inexpensive computer for the calculations. A major disadvantage is that a large number of well-analyzed standards may be required for the initial determination of the coefficients. However, where adequate precautions have been taken to ensure correct separation of instrument- and matrix-dependent terms, the correction constants are transportable from one spectrometer to another and, in principle, need only be determined once.

6.4. Fundamental Methods

Since the early work of SHERMAN, there has been a growing interest in the provision of an intensity – concentration algorithm which would allow the calculation of the concentration values without recourse to the use of standards. Sherman's work was improved upon, first by the Japanese team of SHIRAIWA and FUJINO [17] and later, by the Americans, CRISS and BIRKS [18], [19] with their program NRLXRF. The same group also solved the problem of describing the intensity distribution from the X-ray tube [20]. The problem for the average analyst in the late 1960s and early 1970s, however, remained that of finding sufficient computational power to apply these methods. In the early 1970s, DE JONG suggested an elegant solution [21], in which he proposed the use of a large main-frame computer for the calculation of the influence coefficients, then use of a minicomputer for their actual application using a concentration correction influence model.

7. Trace Analysis

One of the problems with any X-ray spectrometer system is that the absolute sensitivity (i.e., the measured *c/s* per % of analyte element) decreases significantly as the lower atomic number region is approached. The three main reasons for this are: first, the fluorescence yield decreases with atomic number; second, the absolute number of useful long-wavelength X-ray photons from a bremsstrahlung source decreases with increasing wavelength; and third, absorption effects generally become more severe with increasing wavelength of the analyte line. The first two of these problems are inherent to the X-ray excitation process and to constraints in the basic design of conventional X-ray tubes. The third, however, is a factor that depends very much on the instrument design and, in particular, upon the characteristics of the detector.

7.1. Analysis of Low Concentrations

The X-ray fluorescence method is particularly applicable to the qualitative and quantitative analysis of low concentrations of elements in a wide range of samples, as well as allowing the analysis of elements at higher concentrations in limited quantities of materials. A measurement of a line at peak position gives a counting rate which, in those cases where the background is insignificant, can be used as a measure of the analyte concentration. However, where the background is significant, the measured value of the analyte line at the peak position now includes a count-rate contribution from the background. The analyte concentration in this case is related to the net counting rate. Since both peak and background count rates are subject to statistical counting errors, the question now arises as to the point at which the net peak signal is statistically significant. The generally accepted definition for the lower limit of detection is that concentration is equivalent to two standard deviations of the background counting rate. A formula for the lower limit of detection LLD can now be derived [22]:

$$\mathrm{LLD} = 3/m\,\sqrt{R_\mathrm{b}/t_\mathrm{b}} \tag{7}$$

where R_b is the count rate at the background angle, t_b the time spent counting the background, and m the sensitivity of the spectrometer.

It is important to note that not only does the sensitivity of the spectrometer vary significantly over the wavelength range of the spectrometer, but so does the background counting rate. In general, the background varies by about two orders of magnitude over the range of the spectrometer. From Equation (7), the detection limit is optimal when the sensitivity is high and the background is low. Both the spectrometer sensitivity and the measured background vary with the average atomic number of the sample. While detection limits over most of the atomic number range lie in the low ppm range, the sensitivity of the X-ray spectrometer falls off quite dramatically towards the long-wavelength limit of the spectrometer due mainly to low fluorescence yields and the increased influence of absorption. As a result, poorer detection limits are found at the long-wavelength extreme of the spectrometer, which corresponds to lower atomic numbers. Thus, the detection limits for elements such as fluorine and sodium are at the levels of hundredths of one percent rather than parts per million. The detection limits for very low atomic number elements such as carbon ($Z = 6$) and oxygen ($Z = 8$) are very poor, typically on the order of 3 – 5 %.

7.2. Analysis of Small Amounts of Sample

Conventional X-ray fluorescence spectrometers are generally designed to handle rather large specimens with surface areas on the order of several square centimeters, and problems occur if the sample to be analyzed is limited in size. The modern wavelength dispersive system is especially inflexible in the area of sample handling, mainly because of geometric constraints arising from the need for close coupling of the sample to the X-ray tube and the need to use an airlock to bring the sample into the working vacuum. The sample to be analyzed is typically placed inside a cup of fixed external dimensions that is, in turn, placed in the carousel. This presentation system places constraints not only on the maximum dimensions of the sample cup, but also on the size and shape of samples that can be placed into the cup itself. Primary source energy dispersive systems do not require the same high degree of focusing, and to this extent are more easily applicable to any sample shape or size, provided that the specimen fits into the radiation-protected chamber. In some instances, the spectrometer can even be brought to the object to be analyzed. Because of this flexibility, analyses of odd-shaped specimens have been almost exclusively the purview of the energy dispersive systems.

In the case of secondary target energy dispersive systems, while the geometric constraints are still less severe than those of the wavelength system, they are much more critical than in the case of primary systems. Where practicable, the best solution for the handling of limited amounts of material is invariably found in one of the specialized spectrometer systems.

8. New developments in Instrumentation and Techniques

8.1. Total Reflection Spectrometry

One of the major problems that inhibits the obtaining of good detection limits in small samples is the high background due to scatter from the sample substrate support material. The suggestion to overcome this problem by using total reflection of the primary beam was made as long ago as 1971 [23], but the absence of suitable instrumentation prevented real progress being made until the late 1970s [24], [25]. The TRXRF method is essentially an energy dispersive technique in which the Si(Li) detector is placed close to (ca. 5 mm) and directly above the sample. Primary radiation enters the sample at a glancing angle of a few seconds of arc. The sample itself is typically presented as a thin film on the optically flat surface of a quartz plate. A beam of radiation from a sealed X-ray tube passes through a fixed aperture onto a pair of reflectors placed very close to each other. Scattered radiation passes through the first aperture to impinge on the sample at a very low glancing angle. Because the primary radiation enters the sample at an angle barely less than the critical angle for total reflection, this radiation barely penetrates the substrate medium; thus scatter and fluorescence from the substrate are minimal. Because the background is so low, picogram amounts can be measured or concentrations in the range of a few tenths of a ppb. can be obtained without recourse to pre-concentration [26]. Ideally, the radiation falling onto the specimen surface should be monochromatic. Unfortunately, in earlier executions of TXRF spectrometers the use of monochromatic source radiation was not possible because of the high intensity loss. This problem was solved with he advent of multilayer monochromators, since these exhibit high reflectivity and produce an intense almost parallel beam [27]. A TXRF spectrometer has been designed to operate with a standard X-ray tube and a multilayer monochromator, and this was found to give a two- to threefold increase in intensity over the normal geometry [28].

8.2. Spectrometers with Capillary Optics

Curved glass capillaries with channel diameters on the order of a few microns can efficiently scatter X-rays through large angles by multiple grazing incidence reflection. This technology generates a very high specific intensity, yielding an increase in intensity of two to three orders of magnitude [29]. The use of capillary optics has opened up tremendous possibilities in energy dispersive X-ray fluorescence. A new

type of X-ray spectrometer has now evolved, broadly categorized as microscopic X-ray fluorescence (MXRF). Earlier versions of MXRF systems simply used an aperture X-ray guide to control the size of the irradiated spot. Use of a monolithic polycapillary optic in place of the original aperture was found to provide more than two orders of magnitude increase in intensity [30]. There are two basic types of MXRF based on capillary optics: the first is based on classical sealed X-ray tube sources, and the second on the use of the synchrotron. As an example, one low-power, portable XRF analyzer, based on this technology [31], allowed the analysis of specimens as small as 30 mm in diameter with detection limits down to 5 x 10^{-5} %. Gormley [32] has described a series of experiments, based on the use of a CCD camera, to better quantify the focusing and transmission characteristics of these capillaries. Another instrument was designed with an 80 mm^2detector [33] and allowed the analysis of small (5 mm) areas of bulky objects. Each of these spectrometers was designed to work with low-power X-ray tubes. At the other end of the source power scale, Vekemans et al. described an instrument based on a rotating anode X-ray tube. This high-efficiency, microscopic X-ray fluorescence system has been utilized for the analysis of 16-20th century brass statues originating from Northern India and Nepal and for the imaging analysis of enamel paints on 17th century Chinese porcelain [34].

8.3. Applications of the Synchrotron

The availability of intense, linearly polarized synchrotron radiation beams [35] has prompted workers in the fields of X-ray fluorescence [36] to explore what the source has to offer over more conventional excitation media. In the synchrotron, electrons with kinetic energies on the order of several billion electron volts (typically 3 GeV at this time) orbit in a high-vacuum tube between the poles of a strong (ca. 1 T) magnet. A vertical field accelerates the electrons horizontally, causing the emission of synchrotron radiation. Thus synchrotron source radiation can be considered as magnetic bremsstrahlung as opposed to the normal electronic bremsstrahlung that is produced when primary electrons are decelerated by the electrons of an atom. It has been found that because the primary source of radiation is so intense, it is possible to use a high degree of monochromatization between source and specimen, giving a source that is wavelength- and, therefore, energy-tunable, as well as being highly monochromatic. There are several different excitation modes that can be used for synchrotron-source X-ray fluorescence spectroscopy (SSXRF) including direct excitation with continuum, excitation with absorber-modified continuum, excitation with source crystal monochromatized continuum, excitation with source radiation scattered by a mirror, and reflection and transmission modes.

Most SSXRF is carried out in the energy dispersive mode. Since all solid-state detectors are count-rate limited, the tremendous radiation flux available from the synchrotron is, in general, not directly useful. The real power of the synchrotron comes from the use of highly conditioned beams, which provide a highly focused, monochromatic beam at the sample. A newer development in the area of beam conditioning for the synchrotron is the use of laterally graded multilayers [37]. The use of X-ray optical multilayers in X-ray instrumentation became widespread in the 1990s, and newer technology based on pulsed laser deposition is resulting in the production of multilayers of uniform thickness with a minimum of columnar thin-film growth. The intensity of the synchrotron beam is probably four to five orders of magnitude greater than the conventional bremsstrahlung source sealed X-ray tubes. This, in combination with its energy tunability and polarization in the plane of the synchrotron ring, allows very rapid bulk analyses to be obtained on small areas. Because the synchrotron beam has such a high intensity and small divergence, it is possible to use it as a microprobe of high spacial resolution (about 10 µm). Absolute limits of detection around 10^{-14} µg have been reported for such an arrangement [38]. Use of monolithic polycapillary X-ray lenses has added an even wider dimension to synchrotron microbeam analysis, and beam sizes down to 4 – 10 µm have been reported [34]. Such systems have been successfully applied in trace element determination [39].

Synchrotron source X-ray fluorescence has also been used in combination with TRXRF. The small divergence of the continuous beam can

be caused to strike the sample at less than the critical angle. Very high signal-to-background ratios have been obtained on employing this arrangement for the analysis of small quantities of aqueous solutions dried on the reflector, with detection limits of < 1 ppb, i.e., 1 pg. [40]. Additional advantages accrue because synchrotron radiation is highly polarized, and background due to scatter can be greatly reduced by placing the detector at 90° to the path of the incident beam and in the plane of polarization. A disadvantage of the SSXRF technique is that the source intensity decreases with time, but this can be overcome by bracketing analytical measurements between source standards and/or by continuously monitoring the primary beam.

κ gamma quantum; particle
λ disintegration constant
σ cross section
τ dead time of detector
φ flux density of radiation (fluency rate)
Φ flux (fluency)

1. Introduction

Activation analysis has, in a few decades, become one of the most important methods for determination of minor (0.1 – 10 mg/g), trace (1 – 100 µg/g), and ultratrace (1 – 1000 ng/g) elements in solid samples. The main advantages of activation analysis are its accuracy and sensitivity (detection limit). Moreover, it is an independent method, i.e., not subject to the same systematic errors as other, more commonly used analytical methods. When a radiochemical separation is applied (after irradiation and prior to measurement) it is not subject to systematic errors due to reagent blanks, sample contamination (after irradiation), and non-quantitative (and even non-reproducible) yield. Precision goes down to a few percent in most favorable cases. The method is applied in the semiconductor industry, medicine, biology, criminology, archaeology, geochemistry, and environmental studies or control. Activation analysis is based on the exposure of a sample to a flux of activating parti-

10.1002/14356007.b05_689

cles or radiation. Irradiation is performed mainly with thermal neutrons (90 %), but fast neutrons (3 %), charged particles (4 %), or photons (3 %) can also be used (figures based on publications in Chemical Abstracts over the last two decades). This induces a nuclear reaction, whereby an excited intermediate is formed, which deexcites in 10^{-14} s by emission of prompt gamma rays, which can be measured, or the prompt emission of another particle [neutron(s), proton, alpha] i.e., nuclear reaction analysis (NRA). However, in activation analysis (AA) the resulting radioactive nuclide is monitored by means of the emitted alpha, beta, gamma or X-ray quanta, or delayed neutrons. The radiation emitted during the decay is measured for the identification and quantification of the target elements.

2. Neutron Activation Analysis

For a number of reasons, neutrons have found the widest applications as bombarding particles in activation analysis. First, the cross sections for reactions of nuclides with neutrons, yielding primarily (n, γ) reactions, but also (n, α); (n, p), (n, 2 n), and (n, n′) reactions, are often large. The type of reaction depends on the energy of the neutron and is chosen individually for each case, on the basis of the following considerations:

1) A suitable reaction product with not too long a half-life (preferably below one year) and with decay parameters compatible with the available counting equipment
2) A sufficiently high cross section
3) The absence of important interfering reactions yielding the same radionuclide
4) Easy treatment of the sample after irradiation (limited matrix activity)

Second, intense neutron sources (nuclear reactors, neutron generators, isotopic sources) were generally available. Third, the high penetration depth of neutrons allows a nearly homogeneous flux density of the entire sample to be analyzed.

2.1. Basic Principles

If a target with n^A nuclides of A per cubic centimeter is placed in a neutron beam φ (number of neutrons $cm^{-2}\ s^{-1}$) then the number of interactions to form nuclei B is given by the reaction rate R ($cm^{-3}\ s^{-1}$)

$$R = \varphi \sigma n^{\mathrm{A}} \tag{1}$$

where σ is the cross section. The general nuclear reaction can be written as follows:

$$\mathrm{A}\,(n, \kappa) \xrightarrow{\lambda} \mathrm{C}$$

where n is a neutron; κ the promptly emitted gamma quantum or particle; λ is the disintegration constant of the radioactive nuclide B produced (equal to $\ln 2/t_{1/2}$; $t_{1/2}$ denotes the half-life of the radionuclide B); and C is the nuclide produced after radioactive decay of B.

From Equation (1) the definition of the cross section σ for this reaction is obtained:

$$\sigma = \frac{\text{Number of interactions}}{\varphi n^{\mathrm{A}}} \tag{2}$$

The cross section is expressed as an area in square centimeters or, more practically, in barn (1 b = 10^{-24} cm^2).

The number N^A of target nuclei is assumed to remain constant, as is the flux density φ throughout the target. Since the nuclides B decay at a rate equal to $-\lambda N^B$,

$$\frac{\mathrm{d}N^{\mathrm{B}}}{\mathrm{d}t} = \varphi \sigma N^{\mathrm{A}} - \lambda N^{\mathrm{B}} \tag{3}$$

If no nuclides B were present before irradiation ($N^B = 0$ for $t = 0$), integration gives, after an irradiation time t,

$$N^{\mathrm{B}} = \frac{\varphi \sigma N^{\mathrm{A}}}{\lambda} \left(1 - \mathrm{e}^{-\lambda t}\right) \tag{4}$$

The absolute decay rate A_0, in terms of the number of decays per second, at the end of the irradiation is given by

$$A_0 = N^{\mathrm{B}} \lambda = \varphi \sigma N^{\mathrm{A}} \left(1 - \mathrm{e}^{-\lambda t}\right) \tag{5}$$

The expression

$$S = 1 - \mathrm{e}^{-\lambda t} = 1 - \mathrm{e}^{\ln(2)\, t/t_{1/2}} \tag{6}$$

is termed the saturation function. After an irradiation time equal to one half-life of B, a saturation of 50 % is obtained. For irradiation times that are much lower than the half-life, the saturation function can be considered approximately linear:

$$S \approx \ln(2)\, t/t_{12} \quad (\text{for } t < 0.1 t_{1/2}) \tag{7}$$

A correction term ($D = \mathrm{e}^{-\lambda t_d}$) must be applied for the decay during the time t_d between the end of irradiation and the measuring time. When the counting (measuring) time is not very short ($t_\mathrm{m} > 0.3\, t_{1/2}$) compared with the half-life, a correction C for decay during the counting period t_m can also be applied. It equals

$$C = \frac{1 - \mathrm{e}^{-\lambda t_\mathrm{m}}}{\lambda t_\mathrm{m}} \tag{8}$$

Finally the counting equipment has a detection efficiency ε, which is usually less than unity. Thus the number of counts N measured after an irradiation time t, a waiting time t_d, and during a counting time t_m becomes

$$N = \varphi \sigma N^\mathrm{A} \left(1 - \mathrm{e}^{-\lambda t}\right) \mathrm{e}^{-\lambda t_\mathrm{d}} \frac{1 - \mathrm{e}^{-\lambda t_\mathrm{m}}}{\lambda} \varepsilon \tag{9}$$

$$= \frac{\varphi \sigma m \theta N_\mathrm{A} S D C \varepsilon}{A_\mathrm{r}} t_\mathrm{m} \tag{10}$$

where m is the mass of the element A; A_r is its relative atomic mass; θ is the abundance of the isotope yielding the radioactive isotope; and N_A is the Avogadro constant.

2.2. Methods of Neutron Activation

Reactor Neutrons. Nuclear reactors are the largest and most often used neutron sources. Neutrons formed in the reactor have a continuous energy spectrum extending from nearly 0 to 15 MeV. Conventionally the neutron spectrum is divided in three components:

1) *Fast or fission neutrons*, produced by the fission of ^{235}U with energies ranging from 0.1 to 15 MeV. The mean energy is ca. 2 MeV. These neutrons give rise to so-called threshold reactions, e.g., (n, p), (n, α), and (n, 2 n).
2) *Epithermal or resonance neutrons* have energies varying from 0.1 MeV down to about 0.5 eV. In the ideal case the epithermal flux Φ_epi is inversely proportional to the neutron energy E

$$\Phi_\mathrm{epi}(E) = \frac{\Phi_\mathrm{epi}}{E} \tag{11}$$

The highest resonance neutron flux is in the reactor core.

3) *Thermal or moderated neutrons* are in thermal equilibrium with the atoms of the moderator, and their velocities of 2200 m/s at 20 °C correspond to an energy of 0.0253 eV.

In some research reactors, pulses of very high neutron flux may be generated by removing the control rods. The neutron flux increases immediately to several times 10^{16} cm^{-2} s^{-1} and falls after ca. 10 ms to a very low value.

Table 1 shows that at most irradiation facilities the highest fluxes belong to thermal neutrons. Fortunately for activation analysis, they are the most useful ones. As shown in Figure 1 for the lower-energy neutrons (up to several hundred electronvolts) the decrease in cross section with increasing energy is roughly proportional to $1/v$ (where v is the velocity of the neutrons). Sometimes superimposed on this smoothly dropping curve are sharp resonance peaks in the epithermal region just above 1 eV. The total cross section for capture of epithermal neutrons is, therefore, the sum of the $1/v$ probability and that associated with these superimposed resonance peaks, and is called the resonance integral I_0. In neutron activation analysis, thermal and epithermal flux are separated by the so-called cadmium cutoff energy E_Cd of 0.55 eV. Cadmium in fact strongly absorbs neutrons with energies of less than 0.55 eV.

Figure 1. Typical excitation function for neutron-induced reaction, illustrating $1/v$ dependency and resonance peaks in epithermal region

Table 1. Typical neutron fluxes at irradiation facilities in research reactors

Irradiation site	Neutron flux, $cm^{-2}\ s^{-1}$		
	Thermal	Epithermal	Fast
Large reactor			
Reactor core	2×10^{14}	3×10^{13}	4×10^{13}
Surrounding moderator	$1-2\times10^{14}$	$0.5-2\times10^{13}$	$0.2-2\times10^{13}$
Small reactor			
Reactor core	5×10^{12}	4×10^{11}	3×10^{12}
Reflector	$0.3-2\times10^{12}$	$0.2-8\times10^{10}$	$0.3-30\times10^{10}$

In Equation (1) and following, the reaction rate can thus be split up according to the Høgdahl convention [29]

$$R=N\left(\Phi_{\mathrm{th}}\sigma_0+\Phi_{\mathrm{epi}}I_0\right) \tag{12}$$

where σ_0 is the tabulated thermal neutron cross section for the corresponding energy (0.0253 eV). The conventional thermal flux is, with a thermal neutron density n

$$\varphi_{\mathrm{th}}=nv0$$

The second term in Equation (12) is the somewhat more complicated solution for the integration of the reaction probability in the epithermal region. The resonance integrals I_0 have been tabulated:

$$I_0=\int_{E_{\mathrm{Cd}}}^{\infty}\sigma_{\mathrm{epi}}(E)\,\frac{\mathrm{d}E}{E} \tag{13}$$

Values of φ_{th} and φ_{epi} can be found by irradiating a nuclide (monitor) with known σ_0 and I_0 in a cylindrical cadmium box with 1-mm wall thickness. Often, gold is used as a monitor. The cross sections for slow neutron reactions are often on the order of several barns and can in some cases be as large as 10^4 barn. The predominant reaction for slow neutrons is the (n, γ) reaction.

Equation (10) allows calculation, to a first approximation, of the detection limit attainable by neutron activation analysis. If a count rate of $A=1\ s^{-1}$ can be detected and $A_r=100$, $S=0.5$, $\sigma=1$ barn, $\varphi=3\times10^{12}\ cm^{-2}\ s^{-1}$, $\varepsilon=0.33$, with θ, D, and C close to unity, a mass of 10^{-9} g of a typical element can be detected; for many elements with larger cross sections or when irradiating at high neutron fluxes, much lower masses can be detected.

When determining a specific element, the *half-life* of the radionuclide to be measured is a very important parameter. For the production of a radioisotope with a half-life of only a few hours or less, the irradiation time should be limited to a saturation of ca. 0.5 – 0.75, to avoid production of much longer-lived radionuclides. The short-lived radionuclides must be measured soon after the end of irradiation. Also, the counting period should not greatly exceed the half-life of the radionuclide. This however, results in poor counting statistics. For really short-lived radionuclides, this drawback can to some extent be overcome by *cyclic activation analysis* which is based on the use of repetitive short irradiations and counting periods, and summing of the γ-ray spectra. Also *pulsed neutron irradiation* enhances the detection efficiency of radionuclides with $t_{1/2}<20$ s. In contrast, to determine elements producing longer-lived radionuclides (e.g., $t_{1/2}>5$ d), much longer irradiation times are required although activation to a high saturation factor is not meaningful. Treatment of the sample and counting should be postponed several days to allow for decay of the shorter-lived radionuclides.

An additional selectivity factor is the neutron energy. By covering the sample with cadmium or boron carbide, the thermal neutrons are filtered out and the sample is activated largely with epithermal neutrons. (Boron has a nearly pure $1/v$ excitation function and is therefore also chosen to filter out thermal low-energy resonance neutrons.) A distinction is made between *thermal* (*TNAA*) and *epithermal neutron activation analysis* (*ENAA*). In the latter, selective activation of a number of elements relative to other interfering elements can be enhanced. ENAA is often advantageous because most of the matrix ele-

ments in geological and environmental samples (e.g., Na, Al, P, K, Ca, Sc, Cr, Mn, and Fe) are activated primarily with thermal neutrons (σ_0), whereas a number of trace or ultratrace elements (e.g., As, Sb, Se, Sn, Co, Ni, Ga, Mo, Ag, Pd, In, Cd, Br, I, Rb, Sr, Cs, Ta, W, Th, U, Pt, and Au) have large resonance integrals (I_0). Not only is the relative activation of many trace elements enhanced, but the overall activity is also generally reduced so that the sample can be measured much closer to the detector, which improves the counting geometry and thus the precision. Since fast neutrons induce threshold reactions, *fast-neutron activation analysis* (*FNAA*) is used primarily for the determination of light elements (O, N, F, P, S, Cl, Si, Mg, Al, Fe), several of which cannot (or can barely) be determined by thermal neutron activation. Although the reactor neutron spectrum covers a wide range of fast-neutron energies, neutron generators are much more appropriate for FNAA.

Neutron Generators. Neutrons can also be obtained by bombarding an appropriate target with ions accelerated to high kinetic energies. In cyclotrons, a typical neutron flux of 2×10^{11} s^{-1} is obtained with a 10-μA beam of 30-MeV deuterons on a thick beryllium target. Muchmore important, however, are the Cockroft – Walton accelerators, called 14-MeV neutron generators, in which neutrons are produced by the ^{3}H (d, n) ^{4}He reaction. The neutrons obtained have an energy of 14.7 MeV and are emitted nearly isotropically from the target. The total neutron yield varies from 10^8 to 10^{12} s^{-1}, which gives a usable flux density for irradiation ca. 20 – 100 times lower. Since neutron generators are rather compact, are not too expensive, and do not need very large shielding, they are used in many research and industrial laboratories. Cross sections, especially for light elements, often range from 10 mb to a few hundred millibarn for (n, p) and (n, α) reactions on light elements, and even up to 2 – 3 b for some (n, 2 n) reactions on heavy elements. With a neutron flux of 10^9 cm^{-2} s^{-1} typical detection limits of 10^{-4} to 10^{-6} g, and for a few elements (F, Si, P, Cu, Br, Ag, Sb) ca. 10^{-7}, can be reached. Disadvantages of FNAA with neutron generators are the many possibilities for producing the same indicator radionuclide from different elements and the large flux gradients.

The determination of oxygen by the reaction ^{16}O (n, p) ^{16}N is most important. The half-life of the indicator radionuclide ^{16}N is only 7.1 s, and it emits high-energy gamma rays ($>$ 6 MeV), which can be measured without the interference of other radionuclides. A detection limit of about 0.005 % can be obtained by using large samples (10 – 100 g).

Isotopic Neutron Sources [30]. Neutrons can also be produced from isotopic sources. They have the unique advantage of being small, portable, and completely reliable, and of having a constant neutron flux and low cost. There is no need for complicated controlling mechanisms, and the shielding can be very limited. Isotopic neutron sources offer interesting analytical perspectives for accurate determination of minor and major constituents.

Their operation is based on releasing neutrons from a target nucleus either by the action of an α particle or a γ quantum, or during spontaneous fission of a transuranic element. Beryllium is mostly used as target material. As an α source, historically ^{226}Ra was used; it has now been replaced by ^{227}Ac, ^{241}Am, or ^{238,239}Pu, and in the future possibly ^{224}Cm. As a γ source, ^{124}Sb is employed ($t_{1/2}$ = 60.2 d). The neutrons emitted have a broad energy spectrum that peaks at ca. 3 – 6 MeV. Paraffin wax is often used as a moderator. The neutron outputs range from 10^6 to 1.5×10^7 s^{-1} Ci^{-1}. In practice, sources of 10^8 neutrons/s are available commercially. The isotope ^{252}Cf disintegrates not only by alpha decay, but also by spontaneous fission, releasing several neutrons in the process. It has a number of advantages over (α, n) sources: the small size of the source, and the close similarity of the neutron spectrum to that obtained from the fission of uranium. The main disadvantage is obviously its relatively short effective half-life of 2.65 a.

Since the obtainable neutron flux density is generally less than 2×10^6 cm^{-2} s^{-1}, elements with cross sections $>$ 10 barn and half-lifes of less than 5 d have typically been determined. Examples are In, Dy, Rh, V, Ag, La, Eu, Mn, I, Br, Co, Ga, Cu, Ir, and Au. They are determined preferentially in matrices that do not activate very much so that nondestructive analyses are possible. Attainable precisions are better than 1 %, sometimes as good as 0.1 %.

2.3. Standardization

Standardization (i.e., calibration) is performed by Equation (10), which shows that m, the mass of the element to be determined, can be calculated from the measured activity. In practice, this is rarely done because although the values for θ, N_A, A_r, S, D, $C(\lambda)$, and t_m are known with good accuracy for all radionuclides considered, this is not the case for φ (φ_{th} and φ_{epi}), σ (σ_0 and I_0), and ε. Therefore a *relative or comparator method* is normally applied, although more recently absolute methods have also been used. The relative method is essentially very simple. Each sample is coirradiated with a standard containing known amounts of the elements to be determined. When samples and standards are counted under identical conditions, all these factors may be assumed to cancel out, leaving only the following very simple equation:

$$\frac{m_x}{m_{st}} = \frac{A_x}{A_{st}} \cdot \frac{D_{st}}{D_x} = \frac{A_x}{A_{st}} \frac{\left(e^{-\lambda t_d}\right)_{st}}{\left(e^{-\lambda t_d}\right)_x} \tag{14}$$

where the subscripts x and st denote the unknown and the standard, respectively. This simple relationship is valid only when all other factors are the same or are held constant. For short-lived radionuclides, the sample and the standard are irradiated sequentially. Since the neutron flux cannot be relied on to remain entirely constant with time, the activities measured must be corrected for any flux variation by coirradiating flux monitors. Second, the sample and the standard, even when irradiated simultaneously, are not always exposed to the same neutron flux because vertical or lateral flux gradients may occur. This can be corrected by means of flux-gradient monitors. The standards containing known amounts of the elements to be determined can be mixtures of pure elements or compounds of known stoichiometry. Since in NAA the samples to be irradiated are mostly solid, the mixed standard solutions are spotted on clean paper filters or ultrapure graphite, dried, and finally pressed into pellets with similar geometry to the sample. To avoid problems associated with the preparation of these standards, reference materials or other "in-house standard materials" are often used in NAA.

k_0-Method. The k_0-method has been developed to overcome the labor-intensive and time-consuming work of preparing such multielement standards when routine multielement or panoramic analyses are required. Single comparators have been used for a long time, but they are applicable only to constant experimental parameters of activation and counting. Therefore, the k_0-method is being implemented increasingly in NAA laboratories. It is intended to be an absolute technique in which uncertain nuclear data are replaced by a compound nuclear constant, the k_0-factor, which has been determined experimentally for each radionuclide. This k_0 is given by

$$k_0 = \frac{A_r^* \theta \sigma_0 \gamma}{A_r \theta^* \sigma_0^* \gamma^*} \tag{15}$$

where γ is the relative intensity of the gamma radiation in the decay scheme of the radionuclide and * denotes the comparator. For determination of the k_0-factor, gold was used as comparator, which was coirradiated as dilute Au – Al wire. This Au – Al wire should be coirradiated with each sample. It can, however, be converted to any comparator that is found suitable for coirradiation and that has been coirradiated with gold before. To determine the epithermal-to-thermal flux ratio, coirradiation of a zirconium monitor is suitable. The k_0-factors for 68 elements and their relevant gamma lines of 135 analytically interesting radionuclides have been determined and published by De Corte and coworkers. For nearly all of them, the uncertainly is < 2 %. An overview is given in Table 2 [31–33].

2.4. Sources of Errors

Besides typical analytical errors in sample preparation (contamination, inhomogeneity, inaccurate standards) and errors during counting

(pulse pileup, instability, spectrometric interference, electronic failure, etc.), some systematic bias may also occur during the irradiation step, such as neutron shielding and nuclear interference. By taking the proper measures, these can be avoided or corrected for. *Flux gradients* can be determined experimentally and corrected for. For accurate work, vertical and horizontal gradients should be measured for the different types of flux (e.g., thermal, epithermal, and fast). When relatively large samples or standards with large absorption cross sections or resonance integrals are irradiated, nonnegligible *neutron shadowing* or *self-shielding* may also occur.

In addition, *flux hardening* (preferential absorption of low-energy neutrons) and *self-moderation* (unmoderated neutrons are further moderated inside the sample) may occur. Since the correction is difficult to apply for samples with mixed composition and irregular shape, the effect is often avoided by using as small a sample and a standard as possible or by diluting the sample with a material having a low absorption cross section (graphite, cellulose). An internal standard can also be applied.

In thermal neutron activation, the determination of an element ${}^{M}_{Z}\mathrm{E}$ is often based on an (n,γ) reaction producing the radionuclide ${}^{M+1}_{Z}\mathrm{E}$. An (n,p) reaction on nuclide ${}^{M+1}_{Z+1}\mathrm{E}'$ or an (n,α) reaction on nuclide ${}^{M+3}_{Z+2}\mathrm{E}''$ will produce the same indicator radionuclide, resulting in positive errors. This *nuclear interference* depends on the concentration ratios of the elements in the sample, the fast-to-thermal flux ratio, and the cross sections involved, and can be estimated by a simple calculation. The cross sections for (n,p) and (n,α) reactions are usually much smaller than the (n,γ) cross sections. Well-known examples are ${}^{27}\mathrm{Al}\,(\mathrm{n},\gamma)\,{}^{28}\mathrm{Al}$ interference by ${}^{28}\mathrm{Si}\,(\mathrm{n},\mathrm{p})\,{}^{28}\mathrm{Al}$, and ${}^{55}\mathrm{Mn}\,(\mathrm{n},\gamma)\,{}^{56}\mathrm{Mn}$ interference by ${}^{56}\mathrm{Fe}\,(\mathrm{n},\mathrm{p})\,{}^{56}\mathrm{Mn}$.

If the interference is not too important it can be corrected for. If uranium or other fissionable material is present in the sample, the fission products with high fission yields (Sr, Mo, Zr, Ce, Ba) can induce important positive errors. The interference can easily be estimated when the uranium content is known. In FNAA, *secondary interference reactions* may occur when fast neutrons interact with other elements and produce particles that induce a nuclear reaction that forms the same indicator nuclide. These particles are usually protons ejected by fast neutrons from a matrix with a high hydrogen content. Examples are:

${}^{19}\mathrm{F}\,(\mathrm{n},2\,\mathrm{n})\,{}^{18}\mathrm{F}$ interference by: ${}^{17}\mathrm{O}\,(\mathrm{p},\gamma)\,{}^{18}\mathrm{F}$ and ${}^{18}\mathrm{O}\,(\mathrm{p},\mathrm{n})\,{}^{18}\mathrm{F}$

${}^{14}\mathrm{N}\,(\mathrm{n},2\,\mathrm{n})\,{}^{13}\mathrm{N}$ interference by: ${}^{13}\mathrm{C}\,(\mathrm{p},\mathrm{n})\,{}^{13}\mathrm{N}$

2.5. Measuring Equipment

For identification and quantification of the radionuclides produced during the activation step a radiation detector is needed. The major way to select a specific radionuclide is of course by *radiochemical separation.* At the end of the irradiation a nonradioactive carrier of the element to be measured can be added prior to separation. A second parameter used for selection is the *half-life* of the radionuclide. Selection on the basis of the *energy of the emitted radiation* is, however, the most powerful technique. Obviously, detection of the γ- and X-rays is much more suitable for identification and selective for quantification purposes than β-ray detection. Alpha emitters are almost never produced in activation analysis.

Gas-filled detectors, such as ionization chambers, proportional counters, and Geiger–Müller counters (→ Radionuclides, Chap. 4.2.2.1.) are mainly sensitive to β-radiation. They rarely allow any selection on the basis of energy. Gamma counting with a selection for energy is called gamma spectrometry and is performed by means of *scintillation* or *semiconductor detectors* (→ Radionuclides, Chap. 4.2.2.2., → Radionuclides, Chap. 4.3.1.). Currently the gamma spectrometric measurements in neutron activation analysis are only performed with semiconductor detectors. Scintillation counters will therefore be discussed only briefly.

Interaction of γ- or X-rays with matter leads to three effects (→ Radionuclides, Chap. 1.5.1., → Radionuclides, Chap. 4.1., → Radionuclides, Chap. 4.2.): (1) A photoelectric effect in which the entire energy is absorbed by the detector and the result is a photopeak in the spectrum, with a pulse height proportional to the full energy of the gamma radiation. (2) Compton scattering results in a partial absorption of the γ-ray en-

ergy. In the spectrum a continuous background is seen, which can interfere with the measurement of other lower-energy γ- or X-rays. (3) Pair production may result in the escape of one or two annihilation photons, each with an energy of 0.511 MeV. The *efficiency* ε of a detector refers to the ratio of the number of radiations actually detected to the number emitted by the source. In addition a photopeak-efficiency ε_p may be defined as the number of counts recorded under the photopeak. The *energy resolution R* is the ability of the detector to discriminate between two γ- or X-rays of different energy. This resolution is defined as the full width ΔE of the peak at half-maximum (FWHM) (→ Radionuclides, Chap. 4.2.2.3.). For scintillation detectors, it is expressed mostly as a percentage of the energy E corresponding to the centroid of the peak. For semiconductor detectors, it is expressed in energy units (kiloelectronvolts or electronvolts). Finally, the *dead time* τ of the detector is the amount of time required before the detector can recover from an incoming radiation and respond to the next event. In gamma spectrometry the main cause of dead time is not the detector itself but the electronic equipment and, more specifically, the amplifier (i.e. pulse pile up) and the multichannel analyzer (MCA).

Scintillation Detectors. In scintillation detecors the incoming radiation interacts with the material by ionization or excitation. The excited atoms or molecules undergo deexcitation by the emission of a photon of light. This light passes through the optically transparent scintillator material and is guided through a light pipe to a photomultiplier, which converts the light to an electrical signal. The signal is then amplified and fed to a counting or storage system. This can be a single-channel analyzer (SCA) or a multichannel analyzer (MCA). The detection efficiency is excellent. The major drawback of NaI(Tl) scintillators is their poor energy resolution, which is typically 7 % for the 661.6-keV line of ^{137}Cs (Fig. 2). Dead times are important at high count rates. More selective counting can be performed with NaI(Tl) detectors when coincidence or anticoincidence spectrometry is applied by using two or even more detectors.

Figure 2. Comparison of gamma spectrum of ^{137}Cs (gamma energy 661.6 keV) obtained with 7.5×7.5-cm NaI(Tl) scintillation detector (a) and with a 50-cm^3 Ge(Li) semiconductor detector (b)

In charged-particle activation analysis (Chapter 4) pure positron emitters have to be measured by their annihilation photons, emitted simultaneously in a 180° geometry. The sample is then introduced between two NaI detectors, coupled to an SCA to select the photopeak of the 511-keV annihilation photons. The fast SCA output is fed into a coincidence circuit, which selects only coincident signals (typically within 40 ns). The poor energy resolution of the NaI detector is no drawback, while the high detection efficiency (as compared with semiconductor detecors) is an advantage. The NaI detectors are much cheaper than semiconductor detectors (for the same detection efficiency) and do not require liquid nitrogen cooling. The signal-to-noise ratio is much higher for the NaI coincidence set-up, than for a Ge spectrometer, mainly because the noise (background) is much lower.

Semiconductor Detectors. These have a $p-i-n$ diode structure in which the intrinsic region is formed by depletion of charge carriers by applying a reverse bias across the diode. The energy of an electron in a semiconductor material is confined to the conduction and the valence bands, both states separated by forbidden energies. The passage of radiation through the semiconductor may inject sufficient energy to raise an electron from the valence band to the conduction band, thus creating an electron–hole pair. In order for the material to be used as a radiation detector, this electrical charge must be collected. Therefore, several thousand volts

are applied to the detector. Owing to the small amount of energy needed to create an electron–hole pair, a large number of pairs (>300 000 pairs/MeV) is created, with small relative statistical fluctuations. Since the energy resolution of the detector depends on this fluctuation, which can be predicted by Poisson statistics, much better energy resolution is obtained than with scintillation counters. For a highly efficient detector, a large, nearly intrinsic or depletion region must be present. Therefore, the $p-n$ junction is created within a single p or n crystal. Ways to achieve this are the surface barrier detector (used only for detection of charged particles because the depletion region is too small), the lithium-drifted detector [Ge (Li) and Si(Li)], and at present the high-purity or intrinsic germanium detector (HP-Ge). *Ge (Li) detectors* must be cooled constantly at liquid nitrogen temperature, they are still in use but are no longer available. They are more efficient for γ-ray detection than Si (Li) detectors, owing to their higher atomic number Z. *Si (Li) detectors* are sufficiently efficient for detection of X-rays and low-energy γ-rays and must be cooled only during operation to ensure optimum energy resolution. Typical resolutions of Si(Li) detectors are 140–160 eV for the 5.9-keV Mn K line from a ^{55}Fe source.

HP-Ge detectors have the advantage that they can be stored at room temperature and are cooled only during operation to reduce the problem of thermal excitation of electrons. Coaxial p-type detectors and n-type detectors are available. In the *n-type detector* the inner contact is made by diffused lithium, while the outer contact is achieved by ion implantation, which ensures a very thin entrance window (0.3 µm). Thin *planar germanium detectors* (5–20 mm) can also be used to measure low-energy radiation and have the advantage of not stopping the more energetic γ-rays, thereby reducing interference effects such as Compton radiation. *Well-type detectors* are also available with well sizes up to 15 mm in diameter and a depth of 40 mm. For cooling, a cold finger and a large cryostat are needed, which makes semiconductor detectors bulky and difficult to maneuver.

Germanium detectors are characterized by three parameters: resolution, peak-to-Compton ratio, and efficiency. The *resolution* is typically given for the 1332-keV ^{60}Co line and varies from 1.8 keV for the very best to 2.3 keV for the very large detectors. The *peak-to-Compton ratio* is measured as the ratio of the number of counts in the 1332-keV peak to the number of counts in a region of the Compton continuum. Values vary from 30 to 90 for the most expensive model. The efficiency is expressed as a relative efficiency compared with the 7.5×7.5-cm NaI(Tl) scintillation detector. Relative efficiencies of HP-Ge detectors vary from 10 % up to 150 %. The dead time of semiconductor detectors is low, so the count rate is limited largely by the electronic circuit.

Gamma spectrometry is performed mainly by using MCAs, and the relation between the obtained pulse height or corresponding channel number and gamma energy must be established. When an absolute method of standardization is applied, the peak detection efficiency ε_{p} of the detector with surrounding material must also be measured.

For *peak area calculation*, two procedures can be applied in principle: integration or fitting. In *integration*, the number of counts recorded in the channels in which about 90 % of the peak is located is corrected for Compton contribution from other peaks by subtracting the content of an equal number of channels before and after the peak. The method fails, of course, when other peaks are located in the immediate neighborhood or in the case of superimposed peaks. *Fitting procedures* assume a defined shape, either Gaussian or with non-Gaussian distortions (determined from the shape of a well-defined peak in the spectrum).

The overall procedure for the evaluation of γ-ray spectra as part of activation analysis consists of several steps as defined by Erdtmann und Petri [34]:

1) Search for the peaks
2) Calculation of γ-ray energy
3) Calculation of peak areas
4) Calculation of γ-ray emission rates
5) Identification of radionuclides
6) Calculation of decay rates
7) Calculation of amounts of elements

The amount of data to be handled during this evaluation procedure requires the use of computers. At present, the multichannel analyzer not only carries out pulse height analysis but also does most of the data processing. The manufac-

turers of computer-based MCAs usually provide built-in or software programs for the different aforementioned steps.

Obviously the use of a personal computer is an important step toward automation of the analysis. The computer can control the automatic sample changer, the timing of the analysis, counting, storing of the spectra, and finally, data processing.

2.6. Procedures for Activation Analysis

Sample Preparation. As in any other analytical technique, the quality of the final results depends strongly on the care taken during sampling (→ Sampling). Since sample sizes can often be small (2 mg up to 20 g), owing to the high sensitivity of NAA, a well-homogenized material is required. In a number of cases, some preirradiation treatment will be necessary, such as: (1) the removal of water by drying, freeze drying, or ashing for biological materials, or evaporation for liquid samples, to avoid pressure buildup due to evaporation or radiolysis during irradiation; (2) the removal of surface contamination; or (3) perhaps even preconcentration. All of these treatments should be performed in clean environments.

For the irradiation itself, the sample is packed in polyethylene vials for total neutron doses of less than 10^{17} cm^{-2} and in high-purity quartz ampoules for longer irradiations at higher fluxes. The packed samples are transferred to the reactor in containers (rabbits) of aluminum, polyamide, graphite, or high-pressure polyehtylene for low-dose irradiation.

The major advantage of activation analysis, however, is that after irradiation, contamination with nonradioactive material does not introduce more errors. On the contrary, when radiochemical separations are required, an amount of nonradioactive carrier of the element to be separated is added, after irradiation.

Instrumental Neutron Activation Analysis (INAA). A purely instrumental approach is applicable for the determination of many elements (i.e., after irradiation, the sample can be unpacked and the induced radioactivity measured without further treatment). Such a technique has a number of advantages. After decay of the induced activities, the sample is essentially unchanged (nondestructive activation analysis), and is therefore available, in principle, for further investigation. In addition, short-lived radionuclides can be used for the analysis. Tedious chemical separations are not required, which implies reduction of analysis time and avoidance of errors associated with separation. INAA becomes feasible when the activity induced in the sample matrix is not prohibitively high and no single major activity is produced that overshadows that of the other radionuclides. Of course, the differences in half-lifes of various radionuclides can also be exploited by limiting the saturation factor S of interfering long-lived activities or by allowing the short-lived matrix activity to decay before counting. Virtually all instrumental multielement activation analysis is based on high-resolution gamma spectrometry using semiconductor detectors after thermal or epithermal activation of the sample in a reactor or a neutron generator.

INAA is favored especially for many organic, biological, and environmental samples, because the elements O, H, C, N, S, and P are not activated or do not produce gamma emitters. The most abundant minor or trace elements such as Si, Fe, Al, Ca, Mg, and Cl have relatively small cross sections or short half-lifes, the nuclides with the highest activity often being ^{24}Na($t_{1/2}$ = 15.0 h) or ^{82}Br ($t_{1/2}$ = 36 h). Also, a number of metallic matrices can be analyzed purely instrumentally with thermal neutrons. Examples of these metals are Be, Mg, Al, Ca, Ti, V, Ni, Y, Zr, Nb, Rh, Pb, and Bi, some of them after decay of the short-lived matrix activity.

In multielement analysis, choosing the optimal irradiation, cooling, and counting conditions for each element is obviously not feasible, so a compromise must be found. The balance between working up a reasonable number of samples and the desired quality of the analytical results will dictate the mode of the irradiation–counting scheme. A typical scheme has been described for atmospheric aerosols (Fig. 3) [35]. For the *short-lived radionuclides*, irradiation of a 2- to 25-mg sample for a few minutes, together with a flux monitor, is employed. Typically, 10 – 15 elements are determined from this irradiation. *Longer irradiation* of a number of samples, together with a multielement standard

or a flux monitor, is followed by two to three counts after decay times varying from 1 to 30 d. In total, the scheme allows detection of up to 45 elements in favorable cases although, more realistically, about 30 elements can be determined with precisions varying from 2 to 10 %. Shorter and less complicated schemes can be applied at the expense of precision and the number of elements determined. The selectivity for the determination of some elements can be enhanced by applying epithermal, pulsed, or cyclic activation and by counting with low-energy photon detectors or anticoincidence spectrometers.

Radiochemical Neutron Activation Analysis. The ultimate sensitivity and the lowest detection limits are generally obtained when radiochemical separations are performed after irradiation. Chemical treatment of the samples and the standards is aimed at separating the radionuclides formed. The separated fractions are then used in a chemical and physical form suitable for counting. Because the actual amount of radionuclides is very small, a chemical carrier is added before the decomposition step to ensure chemical equilibration with the radionuclide. The next stage is chemical separation using classical methods such as precipitation, distillation, solvent extraction, chromatography, ion exchange, or electrodeposition. Since the amount of carrier added is known and greatly exceeds the amount of the element originally present, the yield of the chemical separation can be determined. Correction of the activity measured is possible.

If clean separation of one radionuclide is achieved, scintillation counting or even β-counting can be performed in principle. Nevertheless, high resolution HP-Ge spectrometry is applied to check the absence of any interfering radionuclide. For most types of samples, such as geological, environmental, and biological materials, typical group separation schemes have been developed and can be found in the literature. For biological samples, the emphasis is on the removal of major activities from ^{32}P, ^{24}Na, and ^{82}Br. In geological samples, rare earth elements or noble metals are often determined after separation. Sometimes carriers or so-called scavengers such as hydroxides of Fe^{3+}, Mn^{4+}, and Sn^{4+} are used to remove interfering activities or to separate the analyte radionuclides.

2.7. Sensitivity and Detection Limits

The smallest amount of an element that can be determined depends on the specific activity produced and the minimum activity measurable with sufficient precision. From Equation (10) the activity produced and measured per gram of an element can be calculated. However, the minimum activity that can be measured depends not only on the decay properties of the radionuclide and on the counting equipment, but also on the background of the detector or the Compton continuum on which the photopeak must be detected in gamma spectrometry. Thus the detection limit of an element for specific irradiation – counting conditions is not immutable since it depends on the presence of other radionuclides.

For measurement results giving a Poisson distribution, as in radioactive decay, the equation used to calculate the standard deviation σ is simply the square root of the number of counts recorded when the number is large. The net signal S is obtained as the difference between the measured signal $(S+B)$ minus the background B (e.g., Compton continuum in gamma spectrometry). Thus the statistically derived standard deviation is given as

$$\sigma_s = (S+B+B)^{1/2} \tag{16}$$

The limit of detection depends on whether the background is well known or is not well known as in gamma spectrometry. Curie [36] defines three specific quality levels for a measurement (→ Chemometrics):

1) *Decision limit* L_c is the net signal above which an "observed" signal can be accepted (95 % probability) as detected; L_c equals $1.64\,\sigma_B$ or $2.33\,\sigma_B$; for well-known or not well-known background, respectively
2) *Detection limit* L_D is the "true" net signal that a priori may be expected to be detected; L_D equals $3.29\,\sigma_B$ or $4.65\,\sigma_B$
3) *Determination limit* L_Q is the net signal on which quantitive determination with a precision of 10 % can be performed; L_Q equals $10\,\sigma_B$ or $14.1\,\sigma_B$

Because the sources of errors in NAA are generally known, they can be kept under control. When good laboratory practice is applied,

Figure 3. Irradiation – counting scheme for INAA of air particulates collected on filter paper [35]
φ = Thermal neutron flux; t_{irr} = Irradiation time; t_{d} = Decay time; t_{c} = Counting time

Table 3. Detection limits (units: 10^{-12} g) for INAA under ideal conditions of gamma spectrometry [135 cm^3 Ge(Li) detector, lead shielded] [a] [35]

Na	0.1	Ge	30	Sb	0.02	Tm	2

[a] For detection of radionuclides with $t_{1/2} > 1$ h, irradiation: 48 h at 2×10^{14} cm^{-2} s^{-1} (cadmium ratio =11, i.e., ratio obtained by irradiation without and with cadmium cover); decay time 10 h; counting time 64 h. For detection of radionuclides with $t_{1/2} < 1$ h (marked with *), irradiation: 2 h at 3×10^{11} cm^{-2} s^{-1}; decay time 1 h; counting time 3 h.

the reproducibility and precision can be nearly as good as the counting statistics, in favorable cases as low as 1 – 2 %. Detection limits obtainable by multielement INAA were determined by VERHEYKE and RATH [37] for compromise irradiation – counting conditions but for ideal gamma spectrometry conditions, namely, calculated from a background (Compton continuum) spectrum obtained from very pure irradiated graphite (Table 3). For several elements (Ar, Mn, Sr, Y, Dy) a better sensitivity can be calculated for a shorter decay time. For some elements (F, Mg, Al, V, and Rh) giving rise to radionuclides with half-lifes of less than 10 min no limits are given, although they can be determined with low detection limits after a short irradiation and a fast count. Elements such as S, P, and Bi produce only β-emitters and are therefore absent from the table.

3. Photon Activation Analysis [23],[24]

Photons – often obtained as bremsstrahlung produced in an electron accelerator – with energies varying from 10 to 45 MeV can overcome the threshold of (γ, n), (γ, p), $(\gamma, 2\,\mathrm{n})$, and (γ, α) reactions. Inelastic scattering with low-energy photons leads to short-lived metastable isotopes by (γ, γ') reaction. The light elements C, N, O, and F are determined by (γ, n) reactions, but the reaction leaves the nuclides proton rich, so that a positron emitter is formed. Radiochemical separation or decay curve analysis is needed. Detection limits of $< 1\,\mu\mathrm{g}$ are obtainable. *Instrumental photon activation analysis* (*IPAA*) is possible for heavier elements in the presence of an excess of low atomic number material, because when a bremsstrahlung spectrum is used, the yields of the reactions increase monotonically with increasing atomic number. Typical detection limits range from 0.01 to 1 µg. IPAA has been applied to the analysis of many environmental samples. Typically, about 15 elements can be determined precisely. Photon activation analysis was considered a valuable complement to NAA for the determination of light elements and some heavy elements before charged-particle activation analysis (CPAA) was developed. The major drawback is the limited availability of high-energy electron beams with sufficient intensity.

4. Charged-Particle Activation Analysis

Although NAA and PAA have a few characteristics in common with charged-particle activation analysis (CPAA), there are fundamental differences, owing to the electric charge of the bombarding particle.

In NAA there are endo-ergic reactions [e.g., (n, 2n) or (n, α) in FNAA] as well as exo-ergic reactions [e.g., (n, γ) in TNAA] and this is also the case for CPAA. However, owing to the Coulombic repulsion between a charged particle (CP) and the target nucleus, CPs always require a minimum energy, even for endo-ergic reactions. For CPAA, mono-energetic particles with energies between 5 and 50 MeV are utilized, leading to more nuclear reactions, and more possible nuclear interferences. For a proton energy below 10 MeV, e.g, in general (p, n) and (p, α) reactions are possible. Below 20 MeV also (p, 2n) (p, d) (p, t), (p, ^{3}He), (p, αn) ... reactions have to be considered. For TNAA only (n, γ) reactions have to be considered, nuclear interference from a (n, p) reaction is fairly infrequent.

CPs are slowed down in matter and are all stopped at depth, called the range, being 0.1 to 1 mm. As a consequence the beam intensity is hardly reduced, in contrast to neutron shadowing. Moreover, the induced activity is not related to the mass of the analyte, but to its mass fraction. So standardization (calibration) is very different from NAA.

The *stopping power (S)* is defined as the energy loss (– dE) per unit pathlength (dl) for a particular CP in a particular target:

$$S = \frac{-\mathrm{d}E}{\mathrm{d}l} \tag{17}$$

It depends on the CP energy. As a result the CPs are stopped at a depth, called *range R*. The range is characteristic for a CP, a target, and the CP energy, being mono-energetic.

The equivalent of $\varphi\,\sigma\,N_\mathrm{A}$ in Equations (3) – (10), i.e., the reaction rate in s^{-1}, can be written for an infinitively thin target

$$I\sigma n\mathrm{d}l \tag{18}$$

with I = beam intensity (number of CPs per s), n = number of target nuclides per cm^3, and dl =

thickness (cm) of the infinitively thin target. For a target thicker than the range R, Equation (18) is integrated

$$In \int_0^R \sigma_l \mathrm{d}l = In \int_{E_\mathrm{i}}^0 \frac{\sigma_E \mathrm{d}E}{\mathrm{d}E/\mathrm{d}l} = In \int_{E_\mathrm{t}}^{E_\mathrm{i}} \frac{\sigma_E \mathrm{d}E}{S_E} \tag{19}$$

with E_i the incident CP energy. The sample is supposed to be homogenous. The CP beam intensity is nearly unchanged when penetrating the target, while the CP energy decreases, and consequently the reaction cross section. As the reaction cross section σ is only known as a function of the energy, the stopping power S is used. For a target for which the thickness D is less than the range R, Equation (19) can be rewritten

$$In \int_0^D \sigma_l \mathrm{d}l = In \int_{E_\mathrm{i}}^{E_0} \frac{\sigma_E \mathrm{d}E}{\mathrm{d}E/\mathrm{d}l} = In \int_{E_0}^{E_\mathrm{i}} \frac{\sigma_E \mathrm{d}E}{S_E} \tag{20}$$

with E_0 = outgoing energy. It is clear that the induced activity is proportional to the mass fraction ($\sim n$ in cm^{-3}) of the analyte, in contrast to NAA where it is proportional to the mass of the analyte ($\sim N^A$ dimensionless) in Equations (3) – (10). This difference in dimensions may be suprising for two different modes of activation analysis. However, it is related to (1) the analysed depth, being limited to the range (cm) and (2) the use of beam intensity (in s^{-1}) versus fluency rate (in $\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$) in NAA.

As relative standardization is applied in CPAA, there is no need for absolute activity and beam intensity measurements, nor for absolute data of the reaction cross section σ and stopping power S. If the (relative) cross section is not accurately known, approximations have been developed. The stopping power of any elemental matter can be calculated accurately; for mixtures or compounds the major matrix should be known. If not, an internal standardization method has been developed.

CPAA has been applied successfully for the determination of (trace) elements in the bulk of solid samples, such as pure metals and alloys, semiconductors, geological and solid environmental materials. The method has proven its unique capabilities and outstanding performance in the determination of light elements such as B, C, N, and O. Activation analysis has the unique possibility of removing surface contamination after irradiation and prior to measurement. CPAA has been a milestone, e.g., in the assessment of the bulk oxygen concentration in aluminum.

Recently CPAA has been extended to surface characterization. If it is possible to determine a trace element A in a matrix B at the µg/g level in the bulk of a sample, i.e., in a 1 mm thick layer, then it is also possible to determine the thickness of a mono-elemental layer A on a substrate B (that does not contain A) down to 1 nm. Alternatively, one can determine the composition of such a layer if the thickness is known, and consequently the stoichiometry without any foreknowledge of the thickness.

The principles of CPAA for bulk analysis are summarized in [25] and [26]; for surface characterization in [27] and in [28]. Applications of CPAA for bulk analyses are reviewed in [38]; the feasibility study on surface characterization in [39].

5. Applications

5.1. High-Purity Materials

Since the 1960s, activation analysis has been used intensively for determining trace elements in high-purity materials. Analysis of semiconductor materials, as well as of high-purity metals, obtained by zone refining, and of materials used in nuclear technology, has been one of the major fields of interest in activation analysis. Impurities are known to affect the properties of these materials, even when present in concentrations so low that they can barely be detected by other methods.

INAA is especially suited for the multielement analysis of matrices that, on neutron irradiation, do not produce intense gamma radiation or produce only short-lived ones. Examples of these matrices are graphite, silicon, and aluminum, or their oxides. A typical irradiation counting scheme allows the determination of 55 elements at submicrogram-per-gram concentrations in wafers of silicon [37]. Also, other semiconductor or alloying materials such as Se, Ge, Sb, Te, and ultrapure metals such as Cu, Fe, Ti, Mo, Nb, Ni, Ga Zn, Sn, Zr, Bi, Pb, and noble

metals have been analyzed. Often a postirradiation separation of the matrix activity is required, or a radiochemical separation scheme must be applied based on ion exchange, extraction, or precipitation. Matrix activation can sometimes be avoided by irradiation in a well-thermalized neutron flux or under the cover of cadmium (ENAA).

Photon activation (*PAA*) is used for elements not activated by (n, γ) reaction, with the emphasis on carbon, nitrogen, and oxygen. Detection limits of the order of 20 µg can be obtained.

Even lower limits of detection can be obtained for determining the light elements in semiconductor materials or ultrapure metals by *CPAA*.

The major advantage of activation analysis over nearly all other techniques of analysis – namely, the absence of contamination problems after irradiation – is extremely valuable in this field of application. Preirradiation treatments should be carried out in clean environments, and to further avoid surface contamination, postirradiation washing or etching is highly recommended. Assessing the impurity levels of these typical industrial products by activation analysis is often used in the quality control of manufacturing companies and has therefore been entirely automated and computerized by using a single comparator for calibration.

5.2. Environmental Materials

Neutron activation analysis is one of the major techniques for the determination of many minor and trace elements in a large variety of solid environmental and pollution samples, such as atmospheric aerosols, particulate emissions, fly ash, coal, incineration ash, and sewage sludge. *Instrumental neutron activation analysis* of total, inhalable, or respirable airborne particulate matter collected on a cellulose or membrane filter, or in a cascade impactor on some organic substrate, allows the determination of up to 45 elements by an irradiation – counting scheme similar to the one given in Figure 3. *Radiochemical NAA* is applied only when extremely low limits of determination are required. *Instrumental photon activation analysis* is also complementary to INAA.

The problem in charged-particle activation analysis related to a matrix of unknown composition and degradation (votalization) of the organic matrix during irradiation, has been solved by the development of an internal standardization method.

When applied to water samples, NAA suffers from some severe drawbacks compared with other multielement techniques. Irradiation of water results in radiolysis. Evaporation, freeze drying, adsorption on charcoal, and ion exchange can be used to remove water. A final problem is the interference of intense radiation induced in matrix elements such as Na, K, Cl, Br, and P. Saline water in particular, yields difficult samples for INAA. The preconcentration step may include separation from these elements. A wealth of literature exists describing these environmental applications [40], [41].

5.3. Biological Materials

Activation analysis, particularly with neutrons, is a very effective method for elemental trace analysis of biological materials and plays an important role in studies of trace elements related to health. Because of the limited sensitivity of classical analytical methods, the trace and ultratrace elements that play an important role in biological systems can rarely be determined by the usual methods. Radiochemical NAA has contributed significantly to establishing the normal levels of these elements in blood (total blood, serum, packed cells, and erythrocytes), liver, kidney, lung, muscles, bones, teeth, nerves, and hair and in studies involving disease [42]. It is the method of choice for the determination of Sb, As, Cs, Co, Mn, Mo, Rb, Se, Ag, and V, and is very reliable for Br, Cr, Cu, Hg, I, and Zn, but it lacks sensitivity for Cd, Ni, and Sn [43]. Since radiochemical separations are generally required, a number of group separations using ion exchange or distillation procedures have been developed to remove at least the interfering activities from P, Na, and Br. For a limited number of elements (Co, Cs, Fe, Rb, Se, and Zn), INAA is possible only after a long decay period [44]. Activation analysis offers many advantages for the analysis of foods and plants. INAA of vegetables, meat, fish, and poultry allows the detection of about 20 trace elements [43].

In the last decade speciation (the determination of the species of an element, i.e., its oxidation state or its compounds) has become more important than trace element determination. Speciation analysis is obtained by hyphenated techniques, i.e., coupling of, for example, a chromatographic separation technique to a very sensitive elemental detector. As NAA cannot measure on-line, the role of NAA becomes less important. However, for the development of separation and preconcentration techniques, the use of radiotracers with very high specific activity is an outstanding tool, as these techniques can be developed at realistic concentration levels. Radiotracers produced by charged-particle activation, provide just such a specific activity, as the radionuclide formed is not an (radio)isotope of the element irradiated.

5.4. Geo- and Cosmochemistry

Activation analysis has probably most often been applied in the analysis of geological samples. The NAA results on rare earth elements in meteorites, rocks, and sediments were a significant contribution to the development of modern geo- and cosmochemistry. Also in geological surveys, hundreds of analyses are performed on soil and stream sediments by this technique. Silicate rock, nonsilicate rock, meteorites, minerals, and marble can often be analyzed purely instrumentally. *Epithermal activation* enhances the detectability of a number of interesting elements. When, however, up to 40 elements are to be determined – including the rare earths and the platinum-group elements – a preconcentration or some group separations based on ion exchange and liquid – liquid extraction are applied. A *14-MeV activation* can be applied for the determination of some major elements (O, F, Mg, Al, Si, P, Fe, Cu, Zn). Radioanalysis in geochemistry has been described in [45].

5.5. Art and Archaeology

Archaeologists and museum directors hope that small samples of art objects can be analyzed with high sensitivity, preferentially in a nondestructive way. INAA can usually achieve this. The wealth of information on the concentration of trace elements, obtained by the technique, can often serve as so-called fingerprints for identification or classification purposes. The concentrations may give clues to the provenance of the artifact, the methods of treatment, or the cultural or technological context in which it was made. The artifacts of archaeological interest analyzed range from metals (coins, medals, statuettes, utensils) to nonmetallic artifacts (clays, pottery, marble, obsidian, and paintings). An overview is given in [46].

6. Evaluation of Activation Analysis

When activation analysis is compared with other analytical techniques, it is most suited for the multielemental analysis of minor, trace, and ultratrace elements in solid samples. Often a purely instrumental approach is possible, making the technique nondestructive and leaving the sample intact for other investigations. About 65 % of the elements of the Periodic Table can be determined by *INAA* at concentrations lower than micrograms per gram and, in favorable cases, down to nanograms per gram. The detection of another 20 % is less sensitive, and about 10 – 15 % (mostly light elements) can rarely be detected at all. These can, however, be detected by *FNAA* (F) or *CPAA* (B, C, N, O). The lowest detection limits are always obtained after radiochemical separation. These low detection limits are possible because the technique can be made highly selective. Adjustable parameters are irradiation and waiting time before counting, the nature and energy of the bombarding particle or radiation, and above all the high resolving power of the measurement. A *major benefit* of activation analysis is that it can provide very accurate results for trace concentrations. Contamination from reagents or the laboratory environment is excluded after irradiation. Radiochemical separations can be performed after the addition of inactive carrier, avoiding the need for working with trace amounts. The absorption effects of neutrons during irradiation and of gamma rays during counting are small and generally negligible or can be corrected for. The information obtained is independent of matrix or chemical form. Other sources of error, such as interfering reactions, can generally be calculated and thus

accounted for or avoided. Therefore the reproducibility and the precison can be as good as the counting statistics when good laboratory practice is applied. In favorable cases and for homogeneous samples, it can be as good as 1 – 2 %. For the detection of major contents, a precision of > 0.5 % is rarely achievable. The accuracy depends to a large extent on the calibration procedure. When appropriate standards are used, very accurate results can be obtained, making this a technique preeminently suited for certification purposes. The *major drawbacks* are probably that it is expensive, requires access to nuclear facilities such as a reactor, and is generally slow. Rapid analysis based on short-lived isotopes is possible only in exceptional cases. The cost of the counting equipment is of the order of or much less than most other instruments for trace analysis [atomic absorption spectrometry (AAS), inductively coupled plasma optical emission spectrometry (ICP-OES) and mass spectrometry (ICP-MS), X-ray fluoroescence (XRF), etc.]. To work with radioisotopes, a laboratory must meet legal requirements for radiological safety. An additional disadvantage is the lack of information on the chemical form of the element, which makes speciation studies difficult. Finally, analysis of strongly activated matrices renders the instrumental approach impossible and necessitates the application of important shielding material for the radiochemical separations.

1. Introduction

The term *voltammetry* is used to classify that group of electoanalytical techniques in which the current (ampere) that flows through an electrochemical cell is measured as the potential (volt) applied to the electrodes in the cell is varied. The term is derived from the units of the electrical parameters measured – *volt-am* (pere)-*metry*.

The essential difference between voltammetric and other potentiodynamic techniques, such as constant current coulometry, is that in voltammetry an electrode with a small surface area ($< 10\,\mathrm{mm}^2$) is used to monitor the current produced by the species in solution reacting at this electrode in response to the potential applied. Because the electrode used in voltammetry is so small, the amount of material reacting at the electrode can be ignored. This is in contrast to the case in coulometry where large area electrodes are used so that all of a species in the cell may be oxidized or reduced.

When mercury is used as the electrode in the form of small drops falling slowly from a fine capillary tube in the test solution, the technique has the special name *polarography*. This name is derived from the fact that the electrode can be polarized. An electrode is said to be polarized when no direct current flows across its interface with the solution even though there is a potential difference across this interface. In his work published in 1922 on "Electrolysis with a dropping mercury electrode", JAROSLAV HEYROVSKÝ referred to this phenomenon and called the recorded current – potential polarization curves *polarograms* [1].

The recommendation of IUPAC is that voltammetry is the general term to be used when current – potential relationships are being investigated and that only when a flowing conducting liquid electrode (such as a dropping mercury electrode) is used as the working electrode should the term polarography be used. Polarography, the original technique, is thus a special case of voltammetry.

The *voltammetric cell* is a multi-phase system, in the simplest form designed with two electronic conductors called *electrodes* immersed in an electrolytic conductor (ionic cell solution). The electrolytic conductor consists of the sample solution with the electrochemically active *analyte* and an excess of an inert *supporting electrolyte*. The analyte is an inorganic or organic species and can be present as a cation, an anion or a molecule.

The application of a voltage to the electrodes produces, as the result of an electrode process, an electrical response – a current – from the analyte in the cell solution. The nature and magnitude of this response may be used to both identify and quantify the analyte. Most polarographic and voltammetric procedures utilize electrode processes in which electrons are exchanged between the two phases. Such a process is referred to as a *charge transfer reaction*, because of the flow of charge, i.e., a current, through the electrode.

The small electrode used to monitor the response of the analyte is known as the *working*

10.1002/14356007.b05_705

electrode (WE). Even though only a negligible amount of material is involved in the processes occurring at the working electrode, its small size ensures that a high current density develops at its surface. Consequently, it is the processes which occur at this small electrode that control the current flow through the cell. The WE may be constructed from a wide variety of conduction materials, preferably of mercury and graphite, or alternatively of gold and platinum. For polarographic experiments the dropping mercury electrode (DME) is important and for voltammetric investigations the thin mercury film electrode (TMFE), the hanging mercury drop electrode (HMDE), the glassy carbon electrode (GCE), the carbon paste electrode (CPE), the rotating platinum electrode (RPE), and chemically modified electrodes (CME's) may be used.

The second electrode in the simple voltammetric cell, called the *counter electrode* (CE), serves two purposes. It is used to control the potential applied to the working electrode and to complete the circuit for carrying the current generated at the WE. In the former role it must act as a reference electrode.

In modern measuring systems the current carrying role of the counter electrode is separated from its potential control role by introducing the *auxiliary electrode* (AE) as a third electrode of the cell. The addition of the auxiliary electrode means that the counter electrode is now used only to control the potential of the working electrode and so becomes a true *reference electrode* (RE). Two electrodes which are commonly used as reference electrodes for the precise control of the working electrode potential in aqueous media are the silver – silver chloride electrode in a solution of fixed chloride concentration and the saturated calomel electrode or SCE (a mercury – mercurous chloride electrode in a saturated KCl solution). These electrodes are robust, easily constructed and maintain a constant potential. The three electrode system will be discussed in more detail in Chapter 3.

When the voltage applied to the electrodes (WE and AE) is such that no charge transfer reactions are occuring, the working electrode is said to be "polarized". At higher voltages, the polarization of the working electrode disappears as soon as the conditions exist for a charge transfer reaction, $Ox + ne^- \rightleftarrows Red$, to occur at the interface between the electrolyte solution and the WE. The current flow that results from the oxidation or reduction of the analyte is known as a *Faradaic current*. Its magnitude depends on the concentration of the analyte in the sample solution and on the kinetics of all steps in the associated electrode process. Because of the small surface area of the working electrode ($1 - 10\,mm^2$) the current flow is normally in the nA to μA range.

The temporal decrease of the analyte concentration in the interfacial region of the electrode, as a result of reduction or oxidation, is balanced chiefly by diffusion of the analyte from the bulk of the solution. The transport of charged analytes by migration is insignificant in the presence of an excess of supporting electrolyte in the test solution. Normally migration can be neglected if the supporting electrolyte concentration is at least 10^3 times higher than the analyte concentration. However, mass transport to the interface is assisted by convection, facilitated by movement of the solution relative to the electrode, e.g., by stirring or by the action of the mercury dropping from the capillary of the DME.

According to Nernst, diffusion occurs in a stable layer of thickness δ at the interface of the working electrode, i.e., from the electrode surface to some distance into the solution (Fig. 1). Within the Nernst diffusion layer, the decrease of analyte concentration c_a in the sample solution to c_s at the electrode surface is linear and voltage dependent. Convection within the layer is negligible.

Figure 1. Variation of concentration in the Nernst diffusion layer

For evaluating the diffusion-limited electron transfer current, the following equations are important:

1) The general equation for the cell current as a function of the number of moles converted:

$$i = \frac{\mathrm{d}N}{\mathrm{d}t} nFA \tag{1}$$

where N is the number of moles, t the time, n the number of electrons involved in the electrode reaction, F the Faraday constant, and A the surface area of the working electrode;

2) Fick's first law

$$\frac{\mathrm{d}N}{\mathrm{d}t} = D\left(\frac{\mathrm{d}c}{\mathrm{d}x}\right) \tag{2}$$

where D is the diffusion coefficient, and dc represents the change in concentration over the distance dx from the electrode surface. According to the ideas behind the Nernst diffusion layer, dc/dx can be replaced by $(c_\mathrm{a} - c_s)/\delta$ (Fig. 1). From Equations (1) and (2):

$$i(t) = DnFA\frac{c_\mathrm{a} - c_s}{\delta} \tag{3}$$

The concentration gradient increases with increasing voltage (see c_{s_1} and c_{s_2} in Fig. 1) and reaches its highest value when all active species reaching the electrode by diffusion immediately participate inthe electron transfer reaction. Then $c_s = c_{s_0} = 0$ and Equation (3) becomes

$$i(t) = DnFA\frac{c_\mathrm{a}}{\delta} \tag{4}$$

In this case the cell current is also called the *limiting diffusion current* i_d, whose value remains constant with further increase of voltage; i_lim is accordingly the maximum value of i and, being proportional to the concentration, is important for analytical voltammetry. However, these relations apply only if the thickness of the diffusion layer remains constant during the cell reaction (stationary state). This is true if the electrode is moved at constant velocity (rotating disk or ring electrode) or if the sample solution is stirred or flows past the electrode at constant velocity (flow cell). In such cases and under ideal experimental conditions, when i is plotted against the voltage E, a line parallel to the E axis is obtained on reaching the limiting diffusion current (Fig. 2 A). The relationships change if both electrode phases remain in the stationary state. Without additional convection the thickness of the diffusion layer, and hence dc/dx, changes with time (Fick's second law). In the course of the electrode reaction, as a result of the electrochemical conversion, the diffusion layer thickness increases as $\sqrt{\pi Dt}$. This means that the diffusion current, after reaching the limiting value i_p, decreases with time according to the Cottrell equation:

$$i(t) = DnFA\frac{c_\mathrm{a}}{\sqrt{\pi Dt}} \tag{5}$$

(Fig. 2 B).

Figure 2. Current – voltage curve at electrodes
A) Stationary; B) Nonstationary diffusion layer thickness
Potential ranges for a) Electrode polarization; b) Electrode reaction; c) Limiting diffusion-controlled current i_d and peak current i_p
E_p = Peak potential; $E_{1/2}$ = Half-wave potential

In *polarography* with the DME, the relationships are even more complicated as both the con-

centration gradient and the diffusion layer width change with time. This is a consequence of the growth of the drop and hence the electrode surface area being in the opposite direction to the diffusion direction. With regard to the electrode reaction the two effects are superimposed, the time average being a constant limiting diffusion-controlled current corresponding to Figure 2 A. Further information on i_{lim} is provided by the Ilkovič equation (Section 2.1, Eq. 8).

The signals proportional to the analyte concentration, i_{d} and i_{p}, are analytically important.

Aside from the diffusion current, currents can occur in voltammetric/polarographic studies which are controlled by reaction kinetics, catalysis, and adsorption.

Kinetic Currents. In kinetic currents, the limiting current is determined by the rate of a chemical reaction in the vicinity of the electrode, provided this precedes the cell reaction. Electrochemically inactive compounds are converted into reducible or oxidizable forms (time-dependent protonation and deprotonation processes, formation and decomposition of complexes, etc.). Conversely, during a chemical reaction after the cell reaction, the product of the electrode reaction is converted to an electrochemically inactive form without influence on the current. However, owing to the changed equilibria between the concentrations of the oxidized and reduced forms at the electrode surface, the half-wave and peak potentials are shifted (Section 2.1). In evaluating kinetic effects, cyclic voltammetry can be helpful (Section 2.4).

Catalytic Currents. For analytical studies, catalytic currents, of which two types are known, are of great interest. In the first case the product of the cell reaction is returned, by a chemical reaction, to the initial state of the analyte. As a result, the analyte concentration at the electrode surface is always high, which results in a considerable increase of the limiting current.

The currents based on the catalytic evolution of hydrogen are the best known. The catalysts are electrochemically inactive heavy metals (primarily salts of the platinum group metals) or organic compounds. They lower the hydrogen overvoltage on the mercury working electrode and so shift hydrogen evolution to more positive potentials. The catalytic current associated with this depends, within limits, on the catalyst concentration. Because of the large number of substances that can lower the hydrogen overvoltage, catalytic currents can only be used to determine concentration under controlled conditions.

Adsorption currents arise when the analyte, in its original form or after chemical or electrochemical conversion, is adsorbed on the working electrode. Adsorption and desorption lead to capacitance changes in the electrochemical double layer and so to analytically usable current signals (Section 2.3).

The theoretical principles of voltammetry and polarography are covered in several monographs [1–7].

2. Techniques

Voltammetric measurement techniques have continued to improve. Some of the improvements have had to await the advance of electronics before being used in practical analysis. Methods with modulated direct current (d.c.) ramps, e.g., differential pulse polarography, as well as alternating current (a.c.) and square-wave polarography, etc., are worth mentioning. New possibilities for controlling experiments and evaluating current signals have followed from digital electronics. The basic principles of analytical voltammetry and polarography are still best explained by way of classical d.c. polarography.

2.1. Direct Current Polarography

Direct current polarography (DCP), introduced by Heyrovský in 1923, is characterized by the recording of current – voltage curves in an unstirred sample solution with the DME as the working electrode. With a slow linear change of voltage, stepwise polarograms are obtained, with marked oscillations caused by the growth and fall of the mercury drop. For better evaluation, the curves can be damped with electronic filters (Fig. 3).

The mercury flows with a mass flow rate m (mg/s) and a periodic drop time t_{d} (s) from a glass capillary. The surface area A of the mercury drop is greatest at the end of the drop time and, at time t during the growth of the drop is:

Figure 3. Direct current polarograms
A) Undamped; B) Damped

$$A = k m^{2/3} t^{2/3} \tag{6}$$

With this expression and the Cottrell equation (5), the following relation is obtained for the magnitude of the instantaneous current at time t_d for an individual drop:

$$i = k' m^{2/3} t_d^{1/6} n D^{1/2} c_a \tag{7}$$

The constant k' includes all constant quantities, including the Faraday constant, and also takes account of the conditions for spherical diffusion. In 1935, it was calculated by ILCOVIČ to have the numerical value 0.708.

The mean of the limiting diffusion current in the DC polarogram is obtained from Equation (7) by integration over the entire drop time:

$$i_d = \frac{1}{t_d} \int_0^{t_d} i \cdot dt = 0.607 \cdot n \cdot m^{2/3} \cdot D^{1/2} \cdot t_d^{1/6} \cdot c_a \tag{8}$$

This is the Ilcovic equation, and applies in the voltage range in which all analyte species reaching the electrode surface by diffusion are either reduced or oxidized. The product $m^{2/3} t_d^{1/6}$ is dependent on the particular glass capillary used and is called the capillary constant. The characteristic shape of the DC polarogram can be described by the Nernst equation:

$$E = E'_0 + \frac{RT}{nF} \ln \frac{c_{a_{ox}}}{c_{a_{red}}} \tag{9}$$

on condition that, for the particular electrode potential E, the mean current magnitude at an individual mercury drop is considered. For the case of reduction $Ox + e^- \rightarrow Red$:

$$i = k \left(c_{a_{ox}} - c^0_{a_{ox}} \right) \tag{10}$$

where $c^0_{a_{ox}}$ indicates the concentration of the analyte on the electrode surface (corresponding to c_s in Eq. 3). The same applies for the concentration $c^0_{a_{red}}$, which increases as $c^0_{a_{ox}}$ decreases; i.e., the sum $c^0_{a_{ox}} + c^0_{a_{red}}$ corresponds to the total analyte concentration $c_{a_{ox}}$. For the limiting diffusion current, at which $c^0_{a_{ox}} = 0$ and $c^0_{a_{red}} = c_{a_{ox}}$, it follows from Equation (10) that:

$$i_d = k c_{a_{ox}} \tag{11}$$

Thus:

$$c^0_{a_{ox}} = c_{a_{ox}} - \frac{i}{k} = \frac{i_d}{k} - \frac{i}{k} \tag{12}$$

and:

$$c^0_{a_{red}} = \frac{i}{k} \tag{13}$$

When the expressions for $c^0_{a_{ox}}$ (Eq. 12) and $c^0_{a_{red}}$ (Eq. 13) are inserted in the Nernst equation (9):

$$E = E'_0 + \frac{RT}{nF} \ln \frac{i_d - 1}{i} \tag{14a}$$

or:

$$E = E'_0 + \frac{0.059}{n} \log \frac{i_d - 1}{i} \tag{14b}$$

For $i = i_d/2$, $E = E_{1/2}$ by definition. $E_{1/2}$, the half-wave potential in the DC polarogram is determined by the electrochemical properties of the redox system concerned.

According to Equation (14), the slope of the current curve depends on the electron transfer number n. Conversely, n can be calculated from the slope. However, the slope also depends on the reversibility of the electrode reaction.

If the activity coefficients f_{ox} and f_{red} for $c_{\mathrm{a_{ox}}}$ and $c_{\mathrm{a_{red}}}$ are inserted into the Nernst equation (9) as well as the diffusion coefficients $D_{\mathrm{ox}}^{1/2}$ and $D_{\mathrm{red}}^{1/2}$ (see Eq. 8), there follows for the half-wave potential:

$$E_{1/2} = E_0 - \frac{RT}{nF} \ln \frac{f_{\mathrm{red}} D_{\mathrm{ox}}^{1/2}}{f_{\mathrm{ox}} D_{\mathrm{red}}^{1/2}} \tag{15}$$

As f and D are determined by the composition of the supporting electrolyte solution, the half-wave potential also depends on this composition.

Direct current polarography is a basic method, from which improved analytical techniques of polarography and voltammetry have been developed. With DCP, inorganic and organic analytes can be analyzed with a sensitivity of about 10^{-5} mol/L. For determining several analytes simultaneously, their half-wave potentials must be at least 100 mV apart.

On closer examination of DC polarograms, the current measured in the voltage range of the charge transfer reaction consists of two parts, the true measurement signal and an interference or noise signal. The measurement signal is the diffusion current, whose value depends on the electrode process and which, because of its origin, is called the Faradaic current i_{F}. The interference signal is the charging current or capacitive current i_{C}, which is a consequence of charging the electrochemical double layer. In the case of the DME, the charging current is given by the equation

$$I_{\mathrm{C}} = (\mathrm{d}E/\mathrm{d}t)\, C_{\mathrm{D}} A + (\mathrm{d}A/\mathrm{d}t)\, C_{\mathrm{D}} E \tag{16}$$

where C_{D} is the double layer capacitance per unit area, E the potential applied to the cell and A the area of the electrode. The first term of this equation allows for the effect of the rate of change of the electrode potential on the charging current, while the second term gives the increase in i_{C} due to the growing mercury drop.

With deceasing analyte concentration i_{F} becomes smaller and approaches i_{C}. The $i_{\mathrm{F}} : i_{\mathrm{C}}$ signal-to-noise ratio is the determining factor for the sensitivity of DCP. If more sensitive polarographic determinations are to be performed, this ratio must be increased by using techniques in which either the Faradaic current is enhanced or the charging current is minimized, or where both can be achieved.

During drop growth (drop life t_{d}), i_{F} and i_{C} are subject to changes in opposite directions. As shown in Figure 4, i_{F} increases with increasing surface area of the mercury drop, while i_{C} becomes smaller.

Figure 4. Change with time of i_{F} and i_{C} during the drop life t_{d} with the measurement or sampling interval t_{m} and the mean values $\bar{i}_{\mathrm{F}}$ and $\bar{i}_{\mathrm{C}}$ over the sampled range

Figure 5. Measurement technique of current sampled DC polarography with the static mercury drop electrode as working electrode
(a) Variation of surface area with time for the SMDE; (b) Potential – time profile for the staircase voltage applied to the electrode; (c) Current – potential response (polarogram). t_m Measuring interval; t_{step} Time interval of the voltage step; ΔE_{step} Voltage step of the applied staircase waveform

If the current is not measured over the whole drop life (as in classical DCP), but over a short period of time at the end of the life of a mercury drop where the growth of surface area is least the current averaged over the measurement (sampling) interval t_m has an improved ratio of $i_F : i_C$. This is the basis of the *current sampled DC-polarography* using a linear scan.

Developments in the measurement technique have resulted in a major reduction in the charging current. Firstly, with the introduction of digitally controlled instruments, the linear voltage ramp applied to the electrodes has been replaced with a stepped (staircase) waveform. The voltage steps are synchronized with the drop formation and the current is sampled at the end of the drop life. Since the voltage is constant when the current is measured, there is no contribution to the charging current from this source (see Eq. 16). The second innovation which led to a reduction in the charging current is the *static mercury drop electrode* (SMDE). In this electrode the mercury drop is extruded rapidly and its growth then stopped after which the area of the mercury electrode remains constant. The area – time profile for the SMDE, the potential – time waveform with the sampling period, and the resulting DC polarogram is shown in Figure 5. The current sampled DC polarography (sometimes called Tast Polarography) is not only more sensitive than classical DCP (ca. 5×10^{-7} mol/L), but also leads to polarograms without oscillations.

2.2. Pulse Techniques

With voltammetric pulse methods, Barker and Gardner [31] found very effective means of reducing the unwanted capacitive (noise) current, markedly improving the sensitivity of polarographic and voltammetric determinations.

A periodically changing square-wave potential with constant or increasing amplitude ΔE_p is applied to the working electrode. During the pulse duration t_p, the currents i_F and i_C that flow in response to the potential change ΔE_p decay in different ways. The Faradaic current decreases according to $t^{-1/2}$, (Eq. 5) while the capacitive current decreases according to

$$i_C = \frac{\Delta E_p}{R} \exp\left(-\frac{t}{R \cdot C_D}\right) \tag{17}$$

(Eq. 17 corresponds to the capacitor formula with discharging resistance R and double-layer capacitance C_D). Figure 6 illustrates the variations of i_F and i_C during the duration t_p of the square pulse ΔE_p. If the current is measured only toward the end of the pulse, essentially only i_F is recorded since i_C has effectively decayed to zero.

The methods based on the application of square voltage pulses differ in the frequency and

height of the pulses applied and in the principle of measurement.

Pulse methods may be used with the DME, the HMDE, the SMDE as well as with solid electrodes and the different types of modified electrodes. Except for square-wave polarography, normally only one pulse is applied to each drop in analytical studies with the DME or SMDE. This pulse is synchronized with the drop period and is applied in each case towards the end of the drop life.

Figure 6. Principle of the pulse methods, according to BARKER

Square-Wave Polarography. In the oldest technique of square-wave polarography (SWP), a periodic rectangular alternating voltage with a frequency of 125 Hz and an amplitude in the range of $\Delta E_{\mathrm{p}} = 5 - 30\,\mathrm{mV}$ is superimposed on the linear rising d.c. ramp. The current is sampled over a measurement interval t_{m} near the end of each square-wave half cycle. This current is then amplified and recorded as a function of the applied d.c. voltage. Peak-shaped polarograms are obtained in which the peak current corresponds to the DC polarographic half-wave potential.

Sampling the current near the end of each half cycle ensures that the charging current arising from the sudden step in potential at the beginning of the half cycle has decayed away and does not contribute to the measured current. However, when using the DME, there is still a charging current flowing during t_{m} as a result of the slight increase in area of the mercury drop (see Eq. 16). This is minimized by using a tilted square-wave as shown in Figure 7.

Figure 7. Square-wave alternating voltage and current signals in square-wave polarography
A) Waveform with pulse tilt; B) Capacitive current $i_{\mathrm{C}\sim}$; C) Faradaic current $i_{\mathrm{F}\sim}$
t_{m} = Measuring interval

In the modern version of square-wave polarography the linear d.c. potential ramp is replaced by a d.c. staircase potential and a SMDE replaces the DME. The drop life is synchronized with each step in the staircase potential. The constant potential of each voltage step is modulated with a small amplitude (ΔE_{p}) alternating square-wave voltage of frequency f towards the end of the step as shown in Figure 8.

The current is measured over a number of cycles in the measurement period t_{m}, twice in each cycle, at point 1 at the positive end of the pulse and at point 2 at the negative end. The average of the differences between the current values $i_1 - i_2$ for each measurement cycle is plotted against the potential of the voltage ramp and gives a peak-shaped polarogram, as before.

For reversible electrode processes, the peak current is dependent on the superimposed rectangular voltage:

$$i_{\mathrm{p}} = kn^2 D^{1/2} \Delta E_{\mathrm{p}} c_{\mathrm{a}} \tag{18}$$

where k is constant at a given frequency. The square-wave polarograms shown in Figure 9

highlight the influence of n and ΔE_p on the height and width of the peaks.

Figure 8. Digitally controlled SWP using the SMDE
a) Variation of the mercury drop surface area with the measurement period t_m; b) Potential – time waveform with the measuring points 1 and 2; c) Current potential response (polarogram). Typical values of parameters: $\Delta E_p \sim 25$ mV, $f \sim 125$ Hz (in 40 ms), $\Delta E_{step} \sim 10$ mV, $t_{step} \sim 10$ s

For reversible processes, sensitivities of about 10^{-8} mol/L can be achieved with SWP and the peak-to-peak resolution is 40 – 50 mV. The sensitivity decreases rapidly with increasing irreversibility of the electrode process.

Normally the voltage scan rate of SWP measurements is about 20 mV/s, but much higher scan rates up to 1000 mV/s can readily be programmed making the method ideal for fast voltammetric measurements.

A high scan rate is the characteristic feature of square-wave voltammetry (SWV), first described by Osteryoung and Osteryoung [32]. In this technique the whole measurement process can be carried out with an extremely rapid change of voltage on a single mercury drop. SWV thus enables very short analysis times and is particularly important as a detection method in flow systems.

A relatively large square wave signal of amplitude $\Delta E_p = 50$ mV is superimposed on a stepped voltage ramp (staircase) with voltage steps of about 10 mV. The duration of the square wave cycle is equal to that of the staircase voltage steps t_{step} and is usually within the range 5 – 10 ms.

Figure 9. Dependence of the peak height on the square-wave voltage amplitude ΔE_p and on the number n of electrons transferred, n [4]
a) – c) $n = 1$ (thallium); d) – f) $n = 3$ (bismuth)
a), d) $\Delta E_p = 40$ mV; b), e) $\Delta E_p = 20$ mV; c), f) $\Delta E_p = 10$ mV

As can be seen from Figure 10, two values of current are determined for each square wave cycle. Measurements are made at point 1 at the positive end of the cycle and point 2 at the negative end. The difference between the two current values $i_1 - i_2$ is plotted against the potential of the voltage ramp and gives a peak-shaped current –voltage curve, as in SWP.

The pulse times, which are in the millisecond range, enable the potential to be scanned at extremely high rates of up to 1200 mV/s. Only one mercury drop is required for each measurement process. However, this rapid procedure is achieved at the cost of sensitivity, as the ratio of Faradaic to capacitive currents is lowered by the short pulse times.

The state of development and capability of square-wave polarography/voltammetry has been reviewed [8], [33].

Figure 10. Measurement technique of square-wave voltammetry
ΔE_{step} = Voltage step of the staircase voltage ramp, (ca. 10 mV) ΔE_{p} = Amplitude of superimposed pulse, ca. 50 mV; t_{step} = wave form period, ca. 5 – 10 ms; 1 and 2 Measurement points

Figure 11. Potential – time waveforms and current – potential responses of A) normal pulse polarography and B) differential pulse polarography (typical values of parameter see text)

Normal Pulse Polarography. In normal pulse polarography (NPP), the voltage of the working electrode is changed, not by means of a direct voltage ramp (as in SWP), but by increasing rectangular pulses superimposed on an initial, constant voltage. The application of the pulses is synchronized with the mercury drop and occurs just before the end of the drop life. Only one voltage pulse with a duration of 30 – 60 ms is applied to each drop. The amplitude ΔE_{p} increases from one pulse to the next and reaches a maximum of 1000 mV. To eliminate i_{C} the current measurement is made ca. 10 – 15 ms before the end of the pulse (Fig. 11).

The measured current determined in pulse polarography is plotted against the pulse amplitude and, as in DCP, yields a curve in the form of a wave. The height of the wave is proportional to the analyte concentration, and the half-wave potential corresponds to the DCP value. Peak-shaped curves can be obtained when the current differences between successive pulses are plotted against the voltage. Sensitivities are ca. 10^{-7} mol/L; the peak resolution is reported to be ca. 100 mV.

Differential Pulse Polarography. The most important pulse method is differential pulse polarography (DPP). In this technique a stepped voltage rise (modern staircase technique) is used and a rectangular voltage pulse with constant amplitude ΔE_{p} of 10 – 100 mV is applied to each mercury drop at the end of its drop time; the pulse duration t_{p} is 40 – 60 ms.

As shown in Fig. 11 B two current measurements are made in DPP: the first i_1 at measurement point 1, immediately before the application of voltage pulse and the second i_2 at point 2 near the pulse end. Both measurements are made on the same mercury drop and also over the same surface area, when the SMDE is used as the working electrode. The difference $\Delta i_1 = i_2 - i_1$ is plotted against the applied d.c. voltage (staircase) and gives a peak-shaped polarogram, because $\Delta i_1/\Delta E$ reaches a maximum in the region of $E_{1/2}$.

Determinations by DPP are on average ten times more sensitive than determinations with NPP. The sensitivity of DPP is about 10^{-8} mol/L and for irreversible processes it falls off only slightly to 5×10^{-8} mol/L. The loss of sensitivity by irreversibility is thus smaller than in the case of other pulse methods. For reversible processes the peak height in DP (differential pulse) polarograms is proportional to the concentration to be analyzed, c_{a}:

$$i_p = \frac{n^2 F^2}{4RT} A c_a \Delta E_p \sqrt{\frac{D}{\pi t_p}} \quad (19)$$

and depends not only on the quantities already mentioned, but on the amplitude of the voltage pulse ΔE_p and the pulse duration t_p. The DP polarograms shown in Figure 12 highlight the increase of peak heights with increasing ΔE_p.

Figure 12. Influence of the pulse amplitude on DP polarograms; Pb and Cd (10 mg/L) in acetate buffer solution pH 2.8
a) $\Delta E_p = 10$ mV; b) $\Delta E_p = 25$ mV; c) $\Delta E_p = 75$ mV

The theory, measurement techniques, and analytical applications of pulse methods have been reported [9].

2.3. Alternating Current Polarography

In this technique, a linear voltage ramp is modulated with a sinusoidal alternating voltage of small amplitude ($\Delta E_\sim = 10 - 100$ mV) and low frequency ($f = 5 - 100$ Hz). The superimposed alternating voltage causes an alternating current $i_\sim$, whose size depends on the instantaneous value of the linear voltage ramp, and is greatest at the half-wave potential. On plotting the selectively measured alternating current against the applied voltage, the peak-shaped AC polarogram is obtained (Fig. 13).

In reversible processes, the peak potential of an AC polarogram is identical with the DC polarographic half-wave potential. The peak current is

$$i_p = \frac{n^2 \cdot F^2}{4RT} (2\pi \cdot D)^{1/2} \cdot A \cdot \Delta E_\sim \cdot f^{1/2} \cdot c_a \quad (20)$$

and is thus dependent on the usual variables as well as being influenced by the frequency f, the amplitude $\Delta E_\sim$ of the superimposed alternating voltage and the area of the electrode A. The value of i_p also depends on the reversibility of the cell reaction and decreases with increasing irreversibility. Owing to the high capacitive current component in AC polarography, caused by the periodic charging and discharging of the double layer, the sensitivity is limited to about 10^{-5} mol/L.

Compared with the alternating voltage applied to the electrode, the capacitive current shows a phase shift of 90° ($\pi/2$). Since the Faradaic alternating current $i_{F\sim}$ has a phase shift of only about 45°, the ratio $i_{F\sim} : i_{C\sim}$ and therefore the sensitivity of AC polarographic determinations can be improved by phase-selective rectification. Instruments designed for AC polarography generally have provision for phase selective current measurements to be made (*AC1 polarography*).

By using phase selective measurement of a higher-harmonic alternating current (e.g., 2nd harmonic with a frequency $2f$) increased sensitivity (10^{-7} mol/L) is obtained because of the marked reduction in the capacitive current component of the higher harmonic (*AC2 or second harmonic wave polarography*).

A phase-selective second harmonic wave polarogram is shown in Figure 14. In contrast to the AC1 polarograms, it has two current peaks. For an invariant residual current (Fig. 14 A), the distance between the two current peaks $i_p^+ + i_p^- = i_p$ can be used for analytical purposes. For a rising residual current (Fig. 14 B), the current components i_p^+ and i_p^- are measured over the extrapolated course of the residual current.

Tensammetry is a variant of AC polarography. In this method, the capacitive current component, whose value is determined by the

Figure 13. Waveform and response of AC polarography

Figure 15. Tensammogram
Alternating current polarogram of the supporting electrolyte solution (– – –); Formation of current peaks after addition of a surfactant (—-); $i_{c\sim}$ = Capacitive current; C_D = Double layer capacitance

double layer capacitance, is measured instead of the Faradaic alternating current. Capacitance changes are caused by the adsorption and desorption of surface active compounds at the electrode surface. Commonly, two almost symmetrical current peaks that are particularly well defined and known as tensammetric peaks are obtained. In the potential region between the peaks the compound is adsorbed. As a result, the capacitance of the electrochemical double layer is lowered and the capacitive current is smaller than the current of the supporting electrolyte solution (Fig. 15).

Figure 16. Principle of linear sweep voltammetry (A) and cyclic voltammetry (B)
Top: Variation of voltage with time; Bottom: Resulting current – potential curves

Tensammetric studies are important for the characterization of interfacial problems and for the analysis of surface-active compounds (e.g., surfactants) that are neither reducible nor oxidizable.

2.4. Linear-Sweep and Cyclic Voltammetry

Both linear-sweep voltammetry (LSV) and cyclic voltammetry (CV) are based on recording the current during a linear change of voltage at a stationary working electrode. The rate of change of voltage $v = \mathrm{d}E/\mathrm{d}t$ is relatively high, in the range 1 – 100 mV/s. The difference is that in the case of CV the voltage is returned to the starting potential; CV is therefore also known as triangle-sweep voltammetry.

Figure 16 compares the variation of voltage with time and the response for the two methods. The peak currents, for both LSV and CV, are proportional to the analyte concentration:

$$i_{\mathrm{p}} = k c_{\mathrm{a}} v 1/2 \tag{21}$$

and are influenced by the rate of change of voltage v. The sensitivity of LSV is about 10^{-7} mol/L and the resolution is about 50 mV.

Cyclic voltammetry is mainly used for studying the reversibility of electrode processes and for kinetic observations, and only sometimes for analytical purposes. The voltage cycle illustrated in Figure 16 ensures that the reaction products formed at the potential $E_{\mathrm{p_{red}}}$ on the cathodic path are reoxidized at $E_{\mathrm{p_{ox}}}$ in the anodic sweep.

For a reversible redox process:

$$\Delta E_{\mathrm{p}} = E_{\mathrm{p_{red}}} - E_{\mathrm{p_{ox}}} = \frac{-57}{n}\,\mathrm{mV} \tag{22}$$

the position of the current peak in this case being independent of the voltage scan rate. The two peaks have equal heights. With increasing irreversibility, ΔE_{p} becomes greater. For quasi-reversible processes and for a slow change of voltage, the difference is about (60/n) mV, but it becomes greater for a faster sweep. For totally irreversible processes, the reduction product is not reoxidized, so the anodic current peak is not seen.

Figure 17. Cyclic voltammogram of a reaction with reversible charge transfer and subsequent chemical reaction
First sweep (—-); Second sweep (– – –)

If the reversible charge transfer is followed by a chemical reaction during which an electrochemically active product is formed, a cyclic voltammogram of the type shown in Figure 17 is obtained.

In the first sweep the two peaks $E^1_{\mathrm{p_{red}}}$ and $E^1_{\mathrm{p_{ox}}}$ appear. The ratio of the peak heights is not, however, 1: 1, as would be expected for a reversible process. Rather, $E^1_{\mathrm{p_{ox}}}$ is smaller than $E^1_{\mathrm{p_{red}}}$, since part of the electrolysis product is chemically converted and therefore no longer available for reoxidation. Since the formed product is electrochemically active, a second peak $E^2_{\mathrm{p_{ox}}}$, which corresponds to the oxidation of this product, appears in the complete anodic sweep. In the second sweep an additional cathodic peak $E^2_{\mathrm{p_{red}}}$, which indicates the reduction of the previously oxidized compound, can also be recorded.

Cyclic voltammetry gives information on the redox behavior of electrochemically active species and on the kinetics of electrode reactions as well as offering the possibility of identifying reactive intermediates or subsequent products [10].

2.5. Chronopotentiometry

In voltammetric studies, the current flowing through the working electrode is measured as a function of the applied voltage and the rate at which the voltage is scanned. In chronopotentiometry, the change of potential of the working electrode with time at constant current is followed. Chronopotentiometry has also been called "galvanostatic voltammetry" and can, therefore, be grouped with the methods described in this chapter.

Determinations are usually carried out under stationary conditions. The electrolytic processes occurring when current flows decide the ratio $c_{\mathrm{a_{ox}}} : c_{\mathrm{a_{red}}}$ of the analyte on the electrode surface, which leads to changes of potential according to the Nernst Equation (9). The potential – time plot is illustrated in Figure 18, and depends on the diffusion behavior and analyte concentration.

The time between the steep sections of the curve is called the transition time τ, which, in diffusion- controlled reversible electrode processes, is described by the Sand equation:

$$\tau^{1/2} = \frac{\pi^{1/2} n F D^{1/2}}{2 j_0} c_{\mathrm{a}} \tag{23}$$

where j_0 is the current density (A/cm^2), and $\tau^{1/2}$ corresponds to the limiting diffusion current in DC polarography. At constant j_0, the potential – time function is:

$$E = E_{\tau/4} + \frac{RT}{nF} \ln \frac{\tau^{1/2} - t^{1/2}}{t^{1/2}} \tag{24}$$

with $E_\tau/4 = E_{1/2}$ for a reversible reaction. Chronopotentiograms were traditionally evaluated graphically, which with small transition times is difficult and often inaccurate. It is more convenient to measure the time values – which are proportional to concentration – electronically via the first or second derivative. In this way empirical time values are obtained which always differ to some degree from the theoretical transition times [34].

Figure 18. Chronopotentiometric potential – time curve with the transition time τ

Normal chronopotentiometry has little importance for analysis. Determinations are possible in the range 10^{-4} – 10^{-5} mol/L at best. However, the technique is of use in understanding the methods of stripping chronopotentiometry and potentiometric stripping analysis, which are important in trace analysis.

2.6. Stripping Techniques

The stripping techniques are so-called multistage combined procedures, with the characteristic that the voltammetric or chronopotentiometric determination is preceded by an electrochemical accumulation of analyte. The accumulation occurs on the surface of a stationary working electrode and leads to considerably improved performance. The methods enable analytical studies in the pico-trace range [11–13].

Stripping Voltammetry. The analyte is accumulated, as the metal or in the form of a known compound, by controlled potential electrolysis or adsorption and with constant convection of the sample solution. The subsequent stripping of the preconcentrated species from the electrode occurs voltammetrically as a linear voltage ramp is applied to the electrode, generally using one of the DC, AC, or DP measurement modes. The current peaks in the voltammograms result from either the reduction or oxidation of the accumulated products. Depending on this electrode reaction, a distinction is made between *anodic stripping voltammetry* (ASV) and *cathodic stripping voltammetry* (CSV).

According to the Randles – Sevcik equation:

$$i_p = kn^{3/2}AD^{1/2}vc1/2 \quad (25)$$

the peak height i_p in the stripping voltammogram is (analogous to i_p in the linear sweep and cyclic voltammogram) proportional to the concentration c and is also influenced by the working conditions, particularly by the surface area A of the working electrode and the rate of change of voltage v during the stripping process. The proportionality to concentration relates to the amount of accumulated material or to that part of the electrolysis product which takes part in the stripping process. Consequently, i_p depends on two further influences: the accumulation time and the degree of stripping of the electrolysis product. By careful selection of all parameters, limits of determination can be well below 10^{-8} mol/L. Various means of trace accumulation and determination are used in stripping voltammetry. In the simplest case the analyte is reduced to the metal and accumulated as an amalgam at a stationary mercury electrode (HMDE or TMFE). The determination step proceeds in the reverse direction to the accumulation and is based on the anodic stripping of the metal (reoxidation). This process of ASV is also known as *inverse voltammetry* and can be illustrated as follows:

$$M^{n+} + ne^- + (Hg) \underset{\text{stripping}}{\overset{\text{accumulation}}{\rightleftharpoons}} M^0\,Hg$$

The current profile and the sequence of steps for inverse voltammetric determination of the analyte M^{n+} are shown in Figure 19.

The analyte is deposited from the stirred sample solution at a voltage E_{acc}, as metal on the mercury electrode. The accumulation time is followed by a rest period, during which the solution is unstirred and the cathodic current falls to a small residual value. During the determination step, the voltage is ramped to more positive values (linear sweep, potential scan rate $v = \Delta E/\Delta t$) and, at the appropriate potential, the accumulated metal is reoxidized. The resulting

current – potential curve displays a peak, with peak potential E_p. The height of the peak is proportional to the analyte concentration (Eq. 25).

Figure 19. Stripping voltammetric determination
a) Accumulation time; b) Rest period; c) Determination or stripping step; d) Anodic dissolution of mercury

The results of stripping voltammetric determinations are reproducible if the operating conditions are maintained exactly. This includes reproducible renewal of the electrode surface, uniform stirring of the solution, reproducible electrolysis and rest times, and exact adjustment of the electrolysis voltage and its rate of change.

The electrolysis time, adjusted to the analyte concentration to be determined, is usually 1 – 5 min.

Useful guidance on the selection of a suitable electrolysis voltage E_{acc} is given by the DC or DP voltammogram of the analyte in the particular supporting electrolyte solution. For an electrode reaction with $n = 1$, the voltage should be about 0.15 V more negative than the half-wave or peak potential of the analyte. Consequently, E_{acc} should lie in the voltage range of the limiting diffusion current.

The potentiostatic principle of accumulation electrolysis enables analytes present simultaneously to be determined either individually or together by adjustment of the accumulation potential. Simultaneous determinations require a difference of peak potentials $\Delta E_p > 100$ mV.

Those metals which can be determined are soluble in mercury and form amalgams (Pb, Cu, Cd, Sb, Sn, Zn, Bi, In, Mn, and Tl). Nobler metals such as Hg, Ag, Au, and Pt are also determinable by ASV using inert solid electrodes (metal or carbon electrodes; Chap. 3).

Metal ions such as arsenic(III), selenium, and tellurium (Me_a^{n+}) may be determined by stripping voltammetry after adding a second metal, such as copper (Me_b^{m+}), to the test solution and co-electrolysing the two metals onto the surface of the HMDE. The copper acts as a co-deposition agent and facilitates the deposition of the analyte, Me_a, on the electrode surface as an intermetallic compound. The analyte may then be stripped from the electrode either by oxidation (ASV) or by further reduction (CSV) to an anionic species according to the following reaction scheme.

$$M_a^{n+} + M_b^{m+} + (m+n)\,e^- + (Hg) \longrightarrow M_a^0 M_b^0{}_{(Hg)} \qquad \text{Accumulation}$$

$$M_a^0 M_b^0{}_{(Hg)} \xrightarrow{CSV} M_a^{p-} + M_b^0{}_{(Hg)} - p\,e^-$$

$$M_a^0 M_b^0{}_{(Hg)} \xrightarrow{ASV} M_a^{n+} + M_b^{m+} + (Hg_2^{2+}) + (m+n+2)e^- \qquad \text{Stripping}$$

Arsenic, selenium, and tellurium are three such elements which may be determined by cathodic stripping voltammetry after having been reductively co-deposited with copper [38]. A characteristic of the cathodic stripping voltammograms of these three elements is that only a single current peak, which arises from the further reduction of the deposited analyte to As^{3-}, Se^{2-} or Te^{2-}, respectively, is observed. In this case the determination by CSV is more selective than by ASV, since in the anodic dissolution, additional current signals are obtained, which arise from the oxidation of the copper and possibly also of mercury [35]. Typical stripping voltammograms for the determination of arsenic by both ASV and CSV after deposition from a copper containing solution are shown in Figure 20. The determination limits for the CSV determination of As, Se or Te in the presence of copper were found to be 0.5 µg/L for As and 0.2 µg/L for Se and Te. Note that only As(III) is determined since under these experimental conditions As(V) is not electroactive. The small amount of arsenic present in water samples is mainly in the + 5 oxidation state as a result of oxidation by oxygen. If the test solution contains D-mannitol, As(V) can be reduced electrolytically to As(0). This is the basis of a method for

determining As(V) in the presence of As(III) by cathodic stripping voltammetry [36].

Figure 20. The differential pulse cathodic (a) and anodic (b) stripping voltammograms of arsenic. The cell solution was 0.1 mol/L HCI containing 2×10^3 mol/L Cu^{2+} and 10 µg/L As. Voltage scan rate = 100 mV/s, $E_{acc} = -0.55$ V; $t_{acc} = 1$ min

The technique of CSV can be applied to the determination of anions forming as accumulation products sparingly soluble Hg(I) salts on the electrode surface. These include the halides, pseudohalides, and oxometallates (vanadate, chromate, tungstate, molybdate).

During the subsequent cathode stripping step, the Hg_2^{2+} ion in the sparingly soluble compound is reduced with formation of a voltammetric current peak (Fig. 21). The peak height is proportional to the accumulated amount of the anion to be determined.

Organic substances can also be determined by this indirect procedure, provided they form insoluble Hg_2^{2+} or Hg^{2+} compounds. These are principally thiols, thioureas, thiobarbiturates, dithiocarbamates, and thioamides.

In adsorptive stripping voltammetry (AdSV) metal chelates and organic molecules are accumulated by adsorption at the surface of the working electrode. If these compounds are electrochemically active, i.e., if they are reducible or oxidizable, their subsequent voltammetric determination is possible. By this principle of so-called adsorptive stripping voltammetry, organic and organometallic compounds are determined in the ultra-trace range. This technique is particularly important for the trace analysis of metals that are not readily deposited as the element on mercury electrodes [13].

Figure 21. Determination of anions by CSV

Two approaches have been used to effect the adsorption of metal ions onto the electrode surface as the metal chelate. The simplest is to add an excess of a suitable complexing agent to the test solution prior to the accumulation step. This is the most common approach and is used preferably with mercury or glassy carbon working electrodes. A selection of frequently used complexing agents is listed in Table 1.

An alternative approach is to modify the surface of a glassy carbon, carbon paste or graphite electrode with the complexing agent. The metal ion is then accumulated by reaction with this modified surface (see page 23).

The potentiostatically accumulated species is determined voltammetrically by reduction or oxidation of the central atom or of the ligand of the metal chelate complex or via catalytic hydrogen evolution. Adsorbed organic molecules can be determined in an analogous way by the oxidation or reduction of their electroactive functional groups.

The quantity of the adsorbed species c_{ad} present after the accumulation time t_{acc} on the surface of the mercury drop area A and with the radius r determines the value of the voltammetric peak current $i_{p.}$ Moreover, c_{ad} is propor-

tional to the concentration c_a of the analyte in solution for low surface coverage. For diffusion-controlled processes, which are assumed here in order to simplify the relationships, the following dependence results for the peak in the stripping voltammogram:

$$i_p = kAc_{ad} = kAc_a \left(\frac{D}{r} t_{acc} + 2\sqrt{\frac{D}{\pi}} t_{acc}^{1/2} \right) \quad (26)$$

The peak current increases linearly with $t_{acc}^{1/2}$ until the electrode surface is saturated, and reaches its maximum value at:

$$i_{p(max)} = kAc_{ad(max)} \quad (27)$$

$c_{ad(max)}$ being proportional to the accumulation time $t_{acc(max)}^{1/2}$, and corresponds to the maximum surface coverage. The linear proportionality

$$i_p \sim c_a t_{acc}^{1/2} \quad (28)$$

applies in AdSV only for the lower and middle µg/L range and for short accumulation times $< t_{acc(max)}^{1/2}$. In routine AdSV practice, departures from linearity at fairly high analyte concentrations are controlled, either by dispensing with the usual stirring of the sample solution during accumulation or by dilution of the sample solution. The voltage dependence of the adsorption of neutral molecules is obviously connected with the interaction studied by A. N. Frumkin between the adsorption energy of a surface-active molecule and the value of the electrode potential determined by the surface charge. The zero charge potential in the electrocapillary curve of the mercury is critical for the adsorption of neutral molecules. Negatively charged surface-active ions are chiefly adsorbed at potentials corresponding to the positive branch of this curve, and the cations at potentials that lie in the negative range (see textbooks on electrochemistry).

Stripping Chronopotentiometry (SCP). With stripping chronopotentiometry, as with stripping voltammetry, the preliminary electrolytic accumulation of the analyte significantly increases the sensitivity of the technique. The difference between the two stripping techniques is that, in stripping chronopotentiometry the change of potential of the working electrode with time during the stripping of the electrolysis product (e.g., of a deposited metal) is recorded. Stripping is performed by application of an anodic current. The output is an "inverse" potential – time curve from which the transition time τ is obtained, as this is a function of concentration, analogous to the determination of the peak current i_p in the stripping voltammogram. From a comparison of the two curves in Figure 22 it can be seen that $E_{\tau/4}$ in the stripping chronopotentiogram corresponds to the peak potential E_p in the stripping voltammogram.

Table 1. Complexing agents used for the determination of metal ions by adsorptive stripping voltammetry

Complexing agent	Element
Reduction of the central metal ion	
1,2-Dihydroxybenzene (catechol)	U, Cu, Fe, V, Ge, Sb, Sn, As
1,3-Butanedionedioxime (dimethylglyoxime)	Co, Ni, Pd
8-Hydroxyquinoline (oxine)	Mo, Cu, Cd, Pb, U
2-Hydroxy-2,4,6-cycloheptatriene (tropolone)	Mo, Sn
2,5-Dichloro-3,6-dihydroxy-1,4-benzoquinone (chloranilic acid)	U, Mo, Sn, V, Sb
N-Nitroso-*N*-phenylhydroxylamine (cupferron)	U, Mo, TI
Reduction of the ligand	
o-Cresolphthalexone (OCP)	Ce, La, Pr
5-Sulfo-2-hydrobenzeneazo-2-naphthol (Solochrome Violet RS - SVRS)	Al, Fe, Ga, Ti, Y, Zr, V, TI, Mg, alkali and alkaline earth metals
1,2-Dihydroxyanthraquinone-3-sulfonic acid (Alizarin Red S)	Al
Chromazurol B (MB9, Mordant Blue 9)	Th, U
Catalytic hydrogen evolution	
Formazone	Pt

For the accumulation step, the HMDE and the TMFE are mainly used. The transition times for determinations by stripping chronopotentiometry at these electrodes are approximately:

$$\tau_{HMDE} = \frac{n \cdot F \cdot c_{amalg} \cdot r_d}{j_0} \quad (29)$$

and

$$\tau_{TMFE} = \frac{nFc_{amalg} \cdot l}{j_0} \quad (30)$$

Here, c_{amalg} is the amalgam concentration after accumulation, r_d the radius of the mercury drop, l the thickness of the mercury film on the electrode surface, and j_0 the current density during the stripping process.

In addition to the time for which the electrolysis potential is applied during the accumulation step, the current density during stripping is also

Figure 22. Comparison of anodic stripping voltammetry and stripping chronopotentiometry

of crucial importance for the limits of detection: as j_0 decreases, the determinations become more sensitive. Limits of detection of ca. 10^{-8} mol/L can be achieved [14].

Figure 23 illustrates the form of the curve for the determination of Cd, Tl, and Pb by stripping chronopotentiometry. The normal potential – time curve (A) is compared with the second derivative (B), from which the transition times can be more simply and accurately obtained. A TMFE coated in situ is used for the accumulation.

For the highest possible sensitivities in stripping chronopotentiometry, and to avoid systematic errors, the sample solutions must not contain oxidizing impurities. Care must therefore be taken to remove the oxygen present in the solution.

This precondition does not apply if the anodic stripping of the accumulated elements is replaced by chemical oxidative stripping. With this variant the technique is known as *Potentiometric Stripping Analysis* (PSA). The working electrode chiefly used for this is the TMFE; the oxidants are Hg^{2+} salts or oxygen dissolved in the sample.

Potentiometric stripping analysis is carried out in several stages. After electrochemical generation of the mercury film on a graphite substrate, the elements to be determined are accumulated by electrolysis at constant potential. The next stage is the oxidation of the deposited elements by the oxidant present in the solution. For this, the current circuit is disconnected. The deposited analytes are stripped in the order of their electrochemical potentials. Anodically deposited precipitates can similarly be stripped by chemical reduction. In all cases, potential – time curves with transition times proportional to concentration result [39–41].

Computer-assisted differential PSA $[E = f\,(\mathrm{d}t/\mathrm{d}E)]$ has become important for the detection of trace elements [42]. Figure 24 compares the normal potential – time curve and the differential curve calculated from it for the simultaneous determination of the four elements.

Figure 23. Simultaneous determination of Cd (5×10^{-7} mol/L), Tl (2×10^{-7} mol/L), and Pb (3×10^{-7} mol/L) in 0.05 mol/L HCl + 0.5 mol/L NaCl + Hg^{2+} 100 mg/L by stripping chronopotentiometry at a TMFE (electrolysis time 10 min; stripping current strength 10 μA) A) Potential – time curve; B) Second derivative [14]

Figure 24. Potential – time curve (A) and differential plot (B) for the determination of zinc, cadmium, lead, and copper by PSA [42]

The theory of stripping chronopotentiometry and differential potentiometric stripping analysis has been reviewed [43].

3. Instrumentation

In modern equipment, the measuring arrangement for polarographic or voltammetric studies consists of a measuring stand and a digital computer. The latter controls the more or less auto-

mated techniques and also analyzes the current signals.

The measuring stand includes the potentiostat locked into analog electronics, the current measurement amplifier, and the digital – analog and analog – digital converters. It also provides a holder for the electrochemical cell, which consists of measuring vessel, electrodes, stirrer, etc.

The *potentiostat* is the voltage source for the DC supply (ca. 4 V) as well as for the superimposition of voltage pulses (NPP and DPP modes) and a sine-wave or square wave alternating voltage (ACP and SWP mode). The basic circuit diagram is shown in Figure 25.

When recording the voltammograms or polarograms using three electrodes, the current is flowing between the working electrode and auxiliary electrode. Compared with the working electrode, the auxiliary electrode has a much greater surface area and thus a smaller current density. The reference electrode is an electrode of the second kind, and the potential of the working electrode is measured against this reference electrode. Potential data for voltammetric and polarographic measurements are reported relative to calomel or silver – silver chloride reference electrodes.

The potentiostatic measuring arrangement with three electrodes (Fig. 25) has superseded the classical measuring arrangement with two electrodes, as with the latter the ohmic potential drop in the sample solution cannot be compensated adequately.

In addition to carbon and the noble metals, the principle material used for the working electrode is mercury, especially for capillary and film electrodes. Because of the high overvoltage of hydrogen on mercury, the latter electrodes ensure a relatively wide potential range for voltammetric/polarographic determinations in various supporting electrolyte solutions. If capillary electrodes are used, the electrode surface can be renewed easily and reproducibly as with the DME, the SMDE and the HMDE.

Dropping Mercury Electrode. The DME, originally proposed by HEYROVSKÝ and used for polarographic studies, consists of a glass capillary, 10 – 20 cm long, with internal diameter 0.04 – 0.1 mm, and is connected by a tube to the mercury storage vessel. The distance between the capillary opening and the mercury level determines the drop time and influences to different degrees the types of current useful for polarographic determinations [1]. The drop time also depends on the electrode potential and the surface tension of the mercury. The surface tension is mainly influenced by the medium, and particularly the solvent, into which the mercury flows. The drop time must be held constant during the measurement and should be 2 – 8 s. In modern instruments the mercury drop is knocked off mechanically by tapping on the capillary at a predetermined constant time.

Figure 26. Drop growth as a function of time; comparison of the DME (A) with the SMDE (B)
Drop fall indicated by arrows

Static Mercury Drop Electrode. The static mercury drop electrode (SMDE) is the preferred electrode for polarographic analysis. Compared with the DME, the drops from this type of electrode can be renewed more frequently, about once or twice per second. A microvalve with opening times of 20 – 200 ms controls the mercury inflow to the capillary. During each open period a mercury drop forms, whose surface area remains constant after the valve closes.

In Figure 26 the increase of the electrode surface area with time during the drop life is compared for the DME and the SMDE. The maximum electrode surface area is reached much more rapidly with the SMDE than with the DME so that the measurement can be carried out at constant electrode surface area. This results in a reduction of the capacitive current and increased analytical sensitivity.

The greatest advantage of this new type of electrode is its ability to function as a stationary and a nonstationary mercury electrode, as well as the possibility of synchronizing the electrode (drop) formation with the programm-control arrangement. The reproducibility of the mercury metering of an SMDE is important for its dependability in operation. In a commercial model (Multi-Mode electrode, Metrohm AG, Switzerland), the mercury is pushed through the capillary by a nitrogen overpressure and a needle valve controls the mercury flow.

Figure 27 shows the construction of the pneumatically controlled Multi-Mode electrode. The electrode is suitable for all voltammetric/polarographic work for which a DME, SMDE, or HMDE is required.

Thin mercury film electrodes (TMFE) are used chiefly for ultra-trace analysis by stripping voltammetry. Glassy carbon has proved itself to be the best substrate onto which a mercury film can be formed. The mercury is deposited by electrolysis, either in a separate operation before the voltammetric determination or, in the case of stripping voltammetry, together with the amalgam-forming metal during the accumulation by electrolysis (in situ coated TMFE, Section 2.6; the mercury film generated should be

1 – 100 µm thick). Voltammetric determinations with the TMFE can be more sensitive than with the HMDE, with improved resolution of neighboring peaks.

Carbon and graphite electrodes are employed principally in the anodic potential range. Glassy carbon electrodes (GCE) and carbon paste electrodes (CPE) are mostly used and are available commercially. They can be used either as stationary or rotating electrodes. *Glassy carbon electrodes* consist of pins or rods 2 – 8 mm diameter, cemented or pressed into a glass or plastic holder. *Carbon paste electrodes* consist of mixtures of spectroscopically pure carbon or graphite powder and water-insoluble, highly viscous organic liquids, e.g., nujol, silicone oil, or naphthalene derivatives. The mixture is ground to a paste, transferred to a glass tube, and expressed from the tube with a piston. The surplus carbon paste must be rubbed off and the surface polished. In voltammetric studies the composition of CPE influences the peak potential and the peak current. Glassy carbon electrodes and carbon paste electrodes are also used as working electrodes in voltammetric detectors for liquid chromatography (→ Liquid Chromatography).

Noble Metal Electrodes. Working electrodes of noble metals are often used for studies in the anodic potential range, or for determining elements with which mercury electrodes interfere (e.g., voltammetric Hg determination at an Au electrode). The electrochemical properties of noble metal electrodes and the reproducibility of the analytical values obtained with them depends on their physical and chemical pretreatment. In comparison with mercury and carbon electrodes, noble metal electrodes are of secondary importance for voltammetric determinations.

Modified Electrodes. When the surface of a working electrode has been chemically changed or treated in order to change its electrochemical properties or to improve its sensitivity and selectivity in an analytical determination, the electrode is referred to as a *modified electrode*. The modification of a voltammetric working electrode, usually a carbon electrode, is done by fixing (immobilizing) reagents on the electrode surface. The reagent that is used to modify the surface is referred as the *modifier*. One of the reasons for the development of modified electrodes is to use them to replace mercury electrodes (for environmental reasons) and so facilitate the further development of voltammetry, and in particular stripping voltammetry, as a "leading edge" technique. A major role of the modifier is to improve the selectivity of the electrode and aid the binding and enrichment of the analyte on the electrode surface.

There are several methods used to modify electrode surfaces: adsorption of reagents on the surface, covalent bonding by reaction between the modifier and functional groups on the electrode surface, incorporation of the modifier within a gel or an electrically conducting polymer film, physically coating the electrode surface with the modifier, e.g., an enzyme, or mixing the modifier with carbon paste.

Carbon paste electrodes have the advantage that the surface can be quickly renewed by simply removing the used surface layer with a tissue or knife. Organic complexing agents, ion exchangers, solid phase extractants and biological materials may be used as modifiers. The modifiers must have a low solubility in the analyte solution and not be electroactive in the working potential range [44].

Modified screen printed electrodes may be prepared either by incorporating the modifier in the carbon containing "ink" or by fixing it to the screen printed electrode surface. A mercury film, electrolytically deposited on a screen electrode has been used to determine heavy metals by ASV or AdSV (e.g., uranium [45]).

Thick-film graphite electrodes can be modified in a similar way to screen printed electrodes to give *thick film modified graphite electrodes* (TFMGEs). After modifying the surface in different ways the electrodes can be used for the stripping voltammetric determination of a number of heavy metals [46].

Microelectrodes. In general, the carbon and mercury working electrodes commonly used in voltammetry have surface areas in the mm^2 range. This means that the linear dimensions of these electrodes are an order of magnitude greater than the thickness of the diffusion layer and the transport of the analyte to the electrode takes place mainly by linear diffusion. However, if the lateral dimensions of the electrode

Figure 28. Interpretation of polarograms and voltammograms
A) Ideal conditions: linear trend of residual current; B) Evaluation of wave heights under nonideal conditions; C) Evaluation of peak currents with strongly curved residual current.
a) Tangent method; b) Evaluation with French curve [5]

are similar to or less than those of the diffusion layer (< 0.1 mm), the diffusion of the analyte to the electrode is then spherical rather than linear. Electrodes with such small dimensions in the lower µm range are referred to as *microelectrodes*. Microelectrodes are becoming more important as working electrodes in voltammetric trace analysis.

The miniaturization of the working electrode results in a higher current density at the electrode surface, but also in small currents flowing in the electrochemical processes. The small area means that the charging current i_c, which is proportional to the area of the electrode (Eq. 16), is also small. Thus as the electrode size decreases, the signal to noise ratio (or sensitivity) increases. In addition, note the very fast response to potential changes (response time) at a microelectrode.

A method of overcoming the problem of measuring the small currents is to join many microelectrodes in parallel and so obtain a much larger current output. An arrangement with many (up to 10 000) single microelectrodes is called a *microelectrode array*. By wiring n single electrodes in any array together in parallel, the output current will be n times that of a single microelectrode, i.e., it can be in the μA range instead of in the pA – nA range. Such an array, while having the advantages of a single microelectrode, produces a current which is large enough to be measured with conventional polarographic equipment.

With microelectrode arrays (mainly made from platinum or carbon by various techniques) it is possible to extend the application of analytical voltammetry to the direct determination of analytes in non-aqueous samples without adding a supporting electrolyte. In stripping voltammetry, the accumulation of the analyte on the electrode can be achieved in a very short time without stirring the solution because of the higher mass transport [47].

Reference and Auxiliary Electrodes. The function of the reference electrode is to monitor the potential of the working electrode and the function of the auxiliary electrode is to complete the electrical circuit for the current generated at the working electrode. The voltage of the auxiliary electrode (Pt wire or graphite rod) with respect to the working electrode is electronically adjusted via the potentiostat to the desired voltage plus the *iR* drop in the solution so that the potential difference between the working and reference electrode is maintained at the required value. Usually the area of the auxiliary electrode is at least 50 times greater than the working electrode.

The potential of the reference electrode must be constant and independent of the composition of the solution. Therefore the reference electrodes used in polarographic and voltammetric practice are electrodes of the second kind, of which the silver – silver chloride electrodes (with potassium chloride of a defined concentration, for example Ag/AgCl, 3 M KCl) are the most important. Previously calomel electrode (for example the saturated calomel electrodes, SCE) were used.

Measuring Cells. The commonest cells have a maximum volume of 25 mL. The vessels are generally made of glass; for demanding trace analyses they consist of quartz or plastic (principally polytetrafluoroethylene, PTFE). Micro-cells with a capacity of 1 mL or less are used for special microanalytical purposes and are constructed individually. Flow cells for analyses in connection with liquid chromatography or for flow injection analysis (FIA) are becoming increasingly important.

4. Evaluation and Calculation

Voltammograms and polarograms are evaluated either graphically or by calculation. For accurate determination of the current value – which is proportional to concentration – from the current wave or from the current peak, the residual current must be subtracted from the signal. For routine analysis, it is often sufficient to interpolate the residual current in the potential range of the voltammetric/polarographic current signal.

Figure 28 compares various practical curves and the methods for their manual interpretation. Such current – voltage curves, and others, can be evaluated more rapidly and with improved accuracy with computer-controlled instruments. The best values are obtained when a polynomial describing the approximate shape of the baseline is used. The coefficients of the polynomial are determined from the experimental points which lie on both sides of the current peak [4].

This evaluation becomes straightforward with equipment in which the current – potential curves are recorded digitally at a high data rate. The first step in the data processing consists of the automatic search for stray experimental data points. These are then eliminated and replaced by the mean value of both neighboring data points. The line of best fit of the current – potential curve is then smoothed within a sliding window along the voltage axis. The smoothing factor that can be applied essentially depends on the number of data points available. The principle of the curve smoothing is illustrated in Figure 29.

Figure 29. Curve smoothing using a voltage window with 9 data points

After smoothing, the curve is automatically differentiated (first derivative) and in this form used for peak recognition. This is achieved by seeking out successive maxima and minima in the differentiated curve (Fig. 30). In the usual voltammetric presentation (increasing negative potentials to the right), a maximum followed by a minimum indicates a reduction peak, whereas the reverse order indicates an oxidation peak. The potentials of the maximum and minimum in the d*i*/d*E* versus *E* plot are noted and the peak width is the difference between these values while the peak potential is the mid-point between them. The qualitative identification of the

analyte is achieved by comparing the peak potential (± a pre-set tolerance) with data stored in the computer memory. For a peak to be identified it must be greater than a pre-determined minimum peak height. After the peak is recognized a baseline is constructed and its value at the peak potential is subtracted from the maximum value of current to give the peak height. The result is presented as a peak or wave height, or as the peak area, all of which are proportional to the concentration of the analyte.

Figure 30. Peak recognition and characterization (Courtesy of Metrohm).
Peak potential = $(E_{max} + E_{min})/2$
Peak width = $E_{min} - E_{max}$

When the baseline is curved the polynomial which approximately describes this baseline is used to establish it mathematically over the potential region across the base of the peak. This potential region is determined from the potentials at which the change in the gradient (becomes more positive) of the current – potential curve occur. The same procedure is used for the evaluation of closely adjacent peaks.

The peak or wave height (h) or peak area (A) calculated by the above procedure can be converted into the desired concentration units either by a *calibration curve* (c versus h or c versus A) or by the method of *standard additions.* When using a calibration curve its slope and linearity must be checked at least daily, also when experimental parameters are changed.

When using the method of standard additions, an aliquot, v, of a standard solution of known analyte concentration c is added (manually with a micropipette or automatically with a motorized burette) to a Volume V of the sample solution in which the analyte concentration is c_a. If h is the peak or wave height of the sample before the standard addition, and H the height after that, then the analyte concentration is given by

$$C_a = hcv/H\,(V + v) - Vh \tag{31}$$

The highest accuracy can be obtained by using several (at least three) standard additions, provided the total concentration always lies within the linear range of the standard curve, when plotting h versus c, and extrapolating the straight line plot back to the c axis. The distance from the origin to the intercept corresponds to c_a.

The reproducibility of voltammetric/polarographic determinations depends not only on the evaluation, but also on the quality of the electrode and the measurement setup. With modern equipment, reproducibility is 0.5 – 2.0 %.

A characteristic source of error is the temperature dependence of voltammetric currents. All equations for the proportionality of polarographic currents to concentration contain the diffusion coefficient, which increases with temperature. The rate constants of preceding and succeeding chemical reactions are also affected by temperature and this must be taken into account when evaluating kinetic and catalytic currents. Electrode reactions that are associated with analyte adsorption processes likewise show a specific temperature dependence. The temperature influence differs and leads to different temperature coefficients for the individual voltammetric methods [48].

In simple diffusion-controlled electrode reactions, deviations between + 1.5 and + 2.2 %/ °C occur. For kinetic and catalytic currents, the temperature coefficients can be up to + 70 %/ °C. Currents that are based on adsorption processes can have negative temperature coefficients, because of decreasing adsorption with increasing temperature.

5. Sample Preparation

Before performing the voltammetric/polarographic determination, in some cases the analyte must be separated from the matrix and from other interfering components, and converted into a measurable form. For total element determinations, sample digestion is normally required. To separate organic analytes from the matrix, extraction methods and chromatographic separation are mainly used.

Heavy metals in association with organic materials are usually in a bound form, from which they must be liberated prior to analysis. This is carried out by dry or wet ashing, whereby the organic matrix must be completely destroyed. To avoid systematic errors, care must be taken in all forms of sample treatment to ensure that the elements to be determined remain completely in the sample and that sample contamination from digestion reagents and vessels is avoided.

Wet digestions are carried out only with high-purity acids. If there is a risk that an element will volatilize, the treatment is carried out under reflux, or better in pressure digesters with quartz or plastic inserts; heating is carried out electrically or by microwave radiation. Sample digestion with nitric acid at high temperatures is favored owing to the increased oxidation power. Figure 31 shows a high-pressure ashing apparatus for the digestion of organic and inorganic samples with acid (HNO_3, HCl, $HClO_4$, H_2SO_4, HF, or mixed acids) in sealed quartz vessels under high pressure (up to 13 MPa) and high temperature (up to 320 °C). The digester is contained in a heated autoclave and filled with nitrogen (ca. 10 MPa) in order to compensate the internal pressure resulting from the digestion reaction.

For the digestion of biological samples, combustion in oxygen (*dry ashing*) can also be useful under suitable conditions. The use of oxygen of highest purity ensures low contamination digestion. Some forms of equipment operate with reflux condensation to avoid losses of elements by volatilization; cooling with liquid nitrogen is particularly suitable. Organic samples can be digested at relatively low temperature in high-frequency oxygen plasmas.

Figure 31. High-pressure ashing apparatus HPA-S (Courtesy of Perkin Elmer)

Voltammetry and polarography are particularly important for the analysis of water samples for heavy metals. In surface waters with organic contamination, they can only be analyzed after digestion. Sampling and storage is of prime importance for correct analytical results.

Water samples are stored in flasks of polyvinyl chloride (PVC) or PTFE, cleaned with 50 % nitric acid before use. The flask is subsequently pre-rinsed with the sample water. Contaminated samples are filtered through membrane filters directly into the sample flask and acidified, e.g., with high purity nitric acid to pH 1 – 2; the filter residue is analyzed separately. Water samples with little or no organic contamination are mixed with the chosen supporting electrolyte and immediately placed in the voltammetric/polarographic set-up.

Contaminated water samples are prepared for electrochemical heavy metal trace analysis either by UV photolysis or by oxidative microwave digestion.

Ultraviolet photolysis is based on the generation of OH radicals, which react with organic compounds and degrade them. Hydrogen peroxide is used as an initiator. The acidified water sample plus hydrogen peroxide is irradiated in quartz vessels. An arrangement for the digestion of one to six samples is shown in Figure 32.

Figure 32. Ultraviolet digester (Courtesy of Metrohm) a) Lamp; b) Digester vessels with stopcocks; c) Cooling chamber with water inlet and outlet; d) Fan; e) Cables

When nitrate-containing samples are UV-irradiated, nitrite is formed by reduction. The voltammetrically active nitrite causes a broad current – voltage peak that can cause interference (e.g., with the determination of zinc). This must be taken into account when examining water samples acidified with HNO_3. Another acid should be used or the nitrite formed should be reduced to nitrogen with sulfamic acid (NH_2SO_3H) immediately after the end of the photolysis.

The complete destruction of organic substances in water samples by UV photolysis depends on the nature and extent of the contamination, and on the intensity of the irradiation. The irradiation time required for waste water samples is usually 1 h (see Fig. 33).

Microwave Digestion. Oxidative microwave digestion is suitable for the rapid degradation of interfering organic substances in surface waters. For this purpose the samples are heated with the oxidizing agent Oxisolv (Merck, Germany) in sealed PTFE vessels in a microwave oven. During the thermal treatment, the pH value of the sample passes through the wide range of pH values (from 11 to 2). Wastewater samples are generally completely digested after 50 – 60 s, so that the voltammetric/polarographic metal trace analysis can be carried out completely free of interference.

Figure 33. Determination of Cd in municipal wastewater by DPASV before (A) and after (B) 1 h UV irradiation [49]

Figure 34. Adsorptive stripping voltammograms for Mo in river water after microwave digestion [50]
a) Untreated sample; b) After microwave digestion + Oxisolv; c) + 2 ng/mL Mo; d) + 4 ng/mL Mo Conditions: 10^{-3} mol/L chloranilic acid, pH 2.7, stirred 1 min, accumulation at −0.2 V
Calculated sample concentration of Mo 1.82 ng/mL

If the metals are determined by the highly sensitive method of adsorptive stripping voltammetry, the digestion time must be increased by 1 – 2 min. Figure 34 shows the voltammograms for the determination of molybdenum in a river water sample; the digestion time was 2×50 s at 260 W microwave power [50].

6. Supporting Electrolyte Solution

The solution for the voltammetric/polarographic determination of elements and organic compounds always contains a supporting electrolyte in order to minimise the migration current and reduce the ohmic voltage drop. The supporting electrolytes used are mainly chlorides, nitrates, and sulfates of Li, Na, K, perchlorates of Li, Na, and salts of tetraalkylammonium bases ($NR_4^+X^-$; R = methyl, ethyl, butyl; X = Cl, ClO_4, Br, I). Moreover, acids (HCl, H_2SO_4), bases (LiOH, NaOH, $NR_4^+OH^-$), and frequently buffer solutions are used as they simultaneously provide for regulation of pH during electrode reactions. Supporting electrolyte concentrations are commonly between 0.1 and 1 mol/L.

If complexation occurs between the analyte and the supporting electrolyte or an added ligand, crucial changes in electrochemical behavior can occur. As a result of complexation, the analyte can become electrochemically inactive, or its behavior may change in such a way that the value of the polarographic half-wave or peak potential becomes more negative. For the simple complexing reaction of a hydrated cation $M(H_2O)_x$ with ligand L and coordination number i:

$$M(H_2O)_x + i\,L \rightleftharpoons ML_i + xH_2O$$

and with the stability constant K of the complex:

$$K = \frac{[ML_i]}{[M]\,[L]^i}$$

the shift of the half-wave or peak potential is given by:

$$\Delta E_{1/2} = \Delta E_p = -\frac{0.059}{n}\log K - \frac{0.059}{n} i \log\,[L] \quad (32)$$

Stability constants and coordination numbers of complexes can be determined from the shift of the polarographic half-wave or peak potentials.

The complexing behavior of supporting electrolytes is analytically important for the resolution of overlapping current signals and for masking interfering sample components. Specific additions of suitable complexing agents are therefore used to improve the selectivity of polarographic determinations, as demonstrated in Figure 35 by the separation of the DPP peaks of Tl/Pb and Cd/In. Similar phenomena are known in multielement determinations by stripping voltammetry. By changing the composition of the supporting electrolyte solution after the simultaneous accumulation by electrolysis and use of suitable complexing agents, the metals are stripped at different potentials and can be determined from their separated peaks [5].

Simple ligands are used as complexing agents, e.g., CN^-, OH^-, NH_3, oxalate, halides, as well as stronger complexing agents, such as ethylenediaminetetraacetic acid (EDTA), citrate, tartrate, etc.

Figure 35. Influence of complexation on the peak separation in differential pulse polarographic curves [5]
10^{-4} mol/L Pb^{2+} and Tl^{+} in 0.1 mol/L KCl (A) and 0.1 mol/L KCl + 0.1 mol/L NaOH (B)10^{-4} mol/L Cd^{2+} and In^{3+} in 0.1 mol/L HCl (C) and 0.1 mol/L HCl + 2 mol/L KI (D)

A high salt content, which can arise after sample digestion or as a result of preceding separation operations, changes the viscosity η of the supporting electrolyte solution and hence the diffusion behavior of the analyte. With increasing salt content the polarographic currents become smaller and displaced to more negative potentials. The peaks in the stripping voltammograms are subject to the same influence, except that the potentials become more positive. Small amounts of inert salts, as can occur in natural samples, generally have no influence on polarographic or voltammetric determinations. Sometimes, as in the case of heavy metal determination in seawater by stripping voltammetry, electrolyte addition becomes superfluous.

The useful voltage range for voltammetric/polarographic determinations depends significantly on the supporting electrolye used. The reduction of the cation of the supporting electrolyte restricts the cathodic working range, as hydrogen evolution from acidic supporting electrolyte solutions depends on the working electrode material. The high overvoltage of H^{+} discharge on mercury is therefore particularly advantageous.

The anodic range is determined by oxidation of water or of the supporting electrolyte anion, as well as by oxidation of the electrode material. Anodic dissolution of mercury can even begin at ca. -0.4 V if anions that form poorly soluble Hg(I) salts are present.

Oxygen must be removed (by deaeration) from the supporting electrolyte solution before each voltammetric/polarographic determination. Oxygen is present in aqueous solutions at ca. 10^{-3} mol/L, depending on the solubility conditions, and is reduced at the working electrode in two stages. The course of the reduction is pH dependent and can be described by the following equations.

1) Reduction in acid solution:

$$O_2 + 2H^+ + 2e^- \longrightarrow H_2O_2$$
$$H_2O_2 + 2H^+ + 2e^- \longrightarrow 2H_2O$$

2) Reduction in alkaline solution:

$$O_2 + 2H_2O + 2e^- \longrightarrow H_2O_2 + 2OH^-$$
$$H_2O_2 + 2e^- \longrightarrow 2OH^-$$

Figure 36. Polarographically usable voltage ranges with Hg, C, and Pt electrodes in various solvents and supporting electrolytes [16]
TEAP = Tetraethylammonium perchlorate

In a DC polarogram the first stage lies between − 0.1 and − 0.3 V, depending on the pH value, and the second stage occurs between − 0.7 and − 1.3 V.

The currents caused by the reduction of oxygen interfere with the current – voltage signals of many analytes. In addition, there is interference due to possible subsequent reactions of the H_2O_2 and of the OH^- ions formed.

The dissolved oxygen is removed by introducing pure nitrogen or argon for 5 – 10 min. Oxygen can also be removed from alkaline solutions by addition of Na_2SO_3.

Inorganic ions are determined almost exclusively in aqueous supporting electrolyte solutions. For organic and organometallic compounds, either aqueous supporting electrolyte solutions mixed with organic solvents or pure organic solvents are used (e.g., alcohols, acetonitrile, propylene carbonate, dimethylformamide, and dimethylsulfoxide). Figure 36 illustrates the potential ranges that are available when using these solvents for anodic and cathodic studies at various working electrodes.

Organic solvents are also used for the extraction of metal chelates, which can then be analyzed in the extract, directly or after adding a polar solvent (in order to raise the solubility of the supporting electrolyte). The procedure known as *extractive voltammetry/polarography* combines the selectivity of partition methods with the possibility of carrying out the determination in organic solvents for many analytes. Using this procedure, the analyte can be simultaneously accumulated and separated from interfering components [15].

7. Application to Inorganic and Organic Trace Analysis

Voltammetry and polarography are used primarily for the trace analysis of inorganic and organic substances. Because of the introduction of the powerful pulse methods and stripping techniques, and of advances in instrumentation, these measurement techniques are also of interest for routine analysis. With modern polarographs the most important voltammetric or polarographic methods can be selected by simple switching. Investigations are therefore possible with the same measuring instrument in a concentration range extending over at least six decades. Ions and molecules can be determined and the resulting signals give qualitative and quantitative information as well as providing insight into the bonding state of the analyte.

Elements and Inorganic Ions. The determination of elements and inorganic ions is based chiefly on reduction and oxidation processes that can take place in combination with kinetic, catalytic, or adsorptive processes. The reduction of simple or complexed ions of metals that are soluble in mercury is usually reversible and leads to readily interpretable current – potential curves. Examples of this are the polarographic determinations of cadmium, copper, thallium, zinc, and lead. Less important for routine analysis is the possibility of determining mercury, silver, and gold voltammetrically at noble metal or carbon electrodes.

Multivalent ions are often reduced in several steps, the mechanism and degree of reversibility of the electrode reaction in most cases being dependent on the composition of the supporting electrolyte solution. Two-step current – potential curves are obtained with

chromium(VI), copper(II), iron(III), molybdenum(VI), and vanadium(V), among others, when suitable supporting electrolyte solutions are used. In a multi-step process, the shape and height of the polarographic wave or peak associated with each step is determined by the number of electrons involved and the reversibility of that step. For analytical purposes, the best sensitivity is obtained when a supporting electrolyte can be found in which the multi-electron exchange occurs in one step at a single potential, resulting in a large single wave or peak in the polarogram. This is illustrated in the DP-polarographic reduction of Cr(VI) shown in Figure 37. In 0.1 mol/L KNO_3 supporting electrolyte (curve A), Cr(VI) is reduced in two steps – firstly to Cr(III) at -0.3 V and then to Cr(II) at -1.2 V. In 0.1 mol/L Na_2EDTA solution (curve B), only one peak is observed corresponding to the four electron reduction of Cr(VI) to Cr(II). Because the three-electron reduction to Cr(III) is irreversible the first peak in curve A is smaller than second peak for the reversible one-electron reduction of Cr(III) to Cr(II). The largest peak, obtained for the four-electron reduction of Cr(VI) to Cr(II) in EDTA solution (curve B), gives a determination limit of 10^{-6} mol/L for the determination of chromium.

For those systems which give well behaved catalytic currents, fairly sensitive polarographic and voltammetric analyses are possible. Examples are the determination of Cr(VI) or Mo(VI) in the presence of nitrate ions or of Fe(III) in the presence of bromate ions. For example, the determination limit for Cr(VI) using DPP can be lowered to ca. 10^{-8} mol/L when Na_2EDTA containing nitrate ions is used as the supporting electrolyte [62]. The Cr(II) formed by the reduction of Cr(VI) at the working electrode is immediately oxidized back to the trivalent state by the nitrate ions and is available to be reduced again in the electrode reaction. Titanium, tungsten, uranium and vanadium can also be determined via catalytic currents in the presence of nitrate or chlorate ions with limits of detection in the µg/L (ca. 10^{-8} mol/L) range [4], [5], [63].

Voltammetric/polarographic methods are suitable both for the simultaneous determination of several analytes and for the determination of single analytes in a sample solution. The possibilities are a consequence of the different potentials at which the peak currents occur and the selection of a suitable voltage range for the analysis. Superimposition or overlap of responses can be eliminated by using another supporting electrolyte. Complexing compounds that are expected to change drastically the redox behavior of the analyte or of the interfering component are suitable for the purpose.

The half-wave potentials determined for selected elements in various supporting electrolyte solutions are compared in Figure 38.

Voltammetric/polarographic methods are not very important for *anion analysis*. Only bro-

mate, iodate, and periodate can be determined by means of polarographic reduction currents. Indirect determinations are possible for those anions that form compounds of low solubility or stable complexes with the Hg_2^{2+} ions formed in the anodic oxidation of the electrode mercury. The current caused by the dissolution of the mercury is proportional to the concentration of these anions in the sample solution. Halides, sulfide, and cyanide can be determined in this way [2], [5].

The most important and most successful application of voltammetry/polarography is the determination of traces of heavy metals in aquatic environmental samples. In only lightly polluted water samples, e.g., in rainwater, drinking water, and seawater, the determinations can often be carried out without further sample preparation, i.e., directly after sampling and adjustment to the required pH value. More heavily polluted samples must be digested, which is usually performed by UV irradiation or in a microwave oven (Chap. 5). There is particular interest in determining those metals whose concentration limits in natural waters or wastewaters are regulated by law and accordingly must be controlled (regulations governing purity of drinking water and wastewater discharge). In DIN 38 406, Part 16, for example (German Standard Method), the Zn, Cd, Pb, Cu, Tl, Ni, and Co concentrations are monitored with the aid of polarographic and voltammetric methods of determination: the procedure is shown in Figure 39.

Figure 39. Flow diagram of the procedure for the polarographic/voltammetric determination of heavy metals in drinking water, groundwater, and surface water according to DIN 38 406 Part 16

The method illustrated in Figure 39 is suitable for determinations between the lower µg/L and middle mg/L ranges. It is used for monitoring the heavy metal content in polluted surface waters and identifies the metal content of solutions as well as the constituents that occur in association with suspended matter or colloidal particles. The generally very small amounts of Co and Ni are determined as dimethylglyoxime complexes by AdSV, while for the other metals DPP or ASV is used, depending on the concentration. Sample preparation depends on the state of the sample.

The methods of voltammetry/polarography are important for determining the concentrations of metals in different oxidation states and for characterizing physicochemical forms of bonding (*speciation analysis*) [17], [18].

The metal content determined by ASV in untreated water samples at natural pH values or in buffered solutions is usually lower than the total content and is described as the biologically available fraction. This is the fraction that is present in the form of labile inorganic complexes or hydrated ions. The metal content combined with organic ligands can only be determined voltammetrically after digestion by UV photolysis. In this way labile and nonlabile or combined metal species can be distinguished.

For the ultra-trace analysis of heavy metals in water the AdSV method, in addition to ASV, is especially powerful [19–21]. The limits of determination are generally in the middle to upper ng/L range; Table 2 gives a survey of the best-known methods.

Most AdSV determinations are carried out, after sample digestion by UV irradiation, by recording cathodic stripping voltammograms. Oxidative microwave digestion with Oxisolv (Chapter 5) is also suitable for sample preparation. Only rarely can trace concentrations of metals in natural samples such as seawater be determined without sample digestion. An example is the determination of uranium using chloranilic acid (2,5-dichloro-3,6-dihydroxy-1,4-benzoquinone) (Fig. 40) as complexing agent. This method enables interference-free determinations in river water samples to be carried out [64].

In contrast, the determination of *platinum* by AdSV with formazone (a condensation product

Table 2. Ultra-trace analysis of metals in natural waters by AdSV

Analyte	Ligand	Electrolyte	Sample pretreatment	Detection limit, ng/L	Reference

of formaldehyde and hydrazine) suffers interference from surface-active substances which can be present even in the purest drinking water at trace level. The unusual feature of the extremely sensitive determination of platinum by AdSV is that the complex of Pt(II) with formazone, after adsorptive accumulation at the HMDE, reduces the hydrogen overvoltage on the mercury surface. At the same time, catalytic currents are developed that can be used for the trace analysis of platinum in the ng/L range [55]. The Pt determination is carried out in water samples after prior UV photolysis, and in biological materials after digestion with HNO_3 in a high-pressure asher.

A further field of application of AdSV is the determination of heavy metal traces in high-purity chemicals. The methods originally developed for water analysis (Table 2) can be used without modification for the purity control of salts of the alkali and alkaline earth metals without having to take account of interference by the salt matrix [66].

Arsenic, selenium, and tellurium can be determined at the trace level by cathodic stripping voltammetry (CSV) after having been reductively co-deposited with copper. A characteristic of the stripping technique of these three elements is that only a single current peak which arises from the further reduction of the deposited analyte to As^{3-}, Se^{2-}, or Te^{2-} is observed. This method is suitable for the determination and speciation of As(V) and As(III) in water samples [36], selenium in minerals [38] and biological samples [68], and for the simultaneous determination of selenium and tellurium (Fig. 41) [37].

Potentiometric stripping analysis (PSA) and chronopotentiometric stripping analysis (CPS) are an alternative techniques that may be used for the determination of metals such as Bi, Cd, Cu, Pb, Sn, Tl, and Zn in water samples [67]. With microprocessor controlled equipment, limits of detection are in the sub-µg/L range. The main advantage of PSA and CPS is that atmospheric oxygen dissolved in an aqueous sample does not have to be removed and that in many cases, including those of wine, urine, and blood, direct determination of cadmium and lead is possible [69–71].

The determination of trace concentrations of heavy metals by stripping voltammetry in body fluids and organ samples is used to assess their physiological function. Methods have been developed for determining toxic metals by ASV and PSA in blood, serum, and urine. Stripping methods are also important for monitoring the heavy metal content in food and drink. The samples are mineralized by dry ashing or by wet digestion. The choice of the appropriate decomposition procedure depends on the type of test and the form of the elements to be determined [4], [5].

Organic compounds. The polarographic and voltammetric determination of organic compounds usually depends on the reduction or oxidation of functional groups. In addition there are some applications where the determination is based on the reaction of organic molecules with the electrode material (mercury) or on the

change in the double layer capacitance associated with the organic species being adsorbed on the electrode surface.

Organic functional groups which are electroactive and the oxidations or reductions of which are the bases of the analytical determinations are listed in Table 3 together with the most important classes of compounds containing these groups. The ranges for the half-wave or peak potentials of selected groups of organic compounds are presented in Figure 42.

Compounds with reducible functional groups predominate. Polyaromatic hydrocarbons, aromatic hydroxy compounds and amines, as well as amides and various nitrogen heterocyclic compounds can be determined anodically. These processes are in many cases pH dependent. Determinations based on redox processes are therefore carried out in buffered solutions. The composition and concentration of the buffer systems generally has no influence on the position of the half-wave or peak potentials. If its concentration is sufficiently high, the buffer simultaneously performs the function of the supporting electrolyte.

The polarographic analysis of aldehydes, organic acids, monosaccharides, and substituted pyridine derivatives is based on kinetic currents, if a rate-determining chemical reaction precedes or follows the actual electrode reaction. Alkaloids, proteins, and many organic sulfur compounds reduce the overvoltage of the hydrogen reaction on the mercury drop electrode and are determined via catalytic hydrogen waves. In native protein molecules, the sulfhydryl and disulfide groups are masked and therefore do not catalyze this electrode process. Not until denaturation by the action of acids, bases, UV radiation, etc., do the catalytic waves appear as a result of exposure of these groups. This phenomenon can be used to determine denatured DNA in natural DNA samples [22].

Indirect polarographic methods are used to determine nitrilotriacetic acid (NTA) and other *polyamino acids*, e.g., EDTA (auxiliary agents for detergents and cleansers). The methods are based on the formation of stable heavy metal complexes with polarographic properties that are different from those of the acids. Bismuth and cadmium salts are used, added in small excess to the sample. For determination of the acids, use is made of the current signals that are caused either by the excess of the metal ions or by a newly formed complex. Both NTA and EDTA are determined according to DIN 38 413 Part 5 after addition of bismuth(III) nitrate to the sample acidified to pH 2 with nitric acid. The polarographic curve is shown in Figure 43.

The determination of *surface-active substances* by tensammetry is particularly sensitive owing to adsorption on the electrode surface and the associated change of the double layer capacitance [23].

Voltammetric trace analysis of *alkaloids and other pharmaceuticals* is carried out after adsorptive accumulation at the electrode surface at constant potential [72]. The compounds that can be determined by AdSV in the submicromolar and nanomolar concentration range also include various pesticides [73–75]. The importance of AdSV for the trace analysis of adsorbable molecules has been summarized [24].

Organic substances that form slightly soluble or coordination compounds with mercury ions (Table 3) are determined polarographically via anodic waves or voltammetrically after anodic accumulation. Agrochemicals containing thiourea are also determined by this CSV technique; the limits of determination are reported to be $10^{-7} - 10^{-8}$ mol/L [76].

Electrochemically inactive organic compounds can be converted into an electrochemically active state by nitration, nitrosation, oxidation, hydrolysis, or some other preliminary chemical reaction, and can then be determined polarographically or voltammetrically. Examples of this are polarographic determinations of alkylbenzenesulfonates in natural water samples after extraction and nitration of the aromatic ring [77] and determinations of beta-receptor blocking agents in tablets after conversion to the corresponding *N*-nitroso derivatives [78].

Aliphatic and aromatic *nitro compounds* are reduced at relatively positive potentials via the hydroxylamines to the corresponding amines. The carcinogenic 4-nitroquinoline-*N*-oxide is determined by DPP in the presence of 4-hydroxyaminoquinoline-*N*-oxide and 4-aminoquinoline-*N*-oxide via the reduction of the nitro group [79]. Nitrazepam, parathion, nitrofurantoin, and the nitroimidazoles in blood plasma or urine are also determined via the reduction of the respective nitro groups.

Table 3. Functional groups for the polarographic and voltammetric determination of organic compounds

Reducible groups	Compounds
$>C=C<$	unsaturated aliphatic and (poly)aromatic hydrocarbons with conjugated double or triple bonds and with multiple double bonds
$-C\equiv C-$	
$-\overset{\vert}{\underset{\vert}{C}}-X$	halogen-substituted aliphatic and aromatic hydrocarbons with the exception of fluoro compounds
$>C=O$	aliphatic and aromatic aldehydes, ketones, and quinones
$-O-O-$	aliphatic and aromatic peroxides and hydroperoxides
$-NO_2$	aliphatic and aromatic nitro and nitroso compounds
$-NO$	
$-N=N-$	azo compounds
$>C=N-$	benzodiazepines, pyridines, quinolines, acridines, pyrimidines, triazines, oximes, hydrazones, semicarbazones
$-S-S-$	disulfides
$>C=S$	thiobenzophenones
$-SO-$	diaryl and alkylaryl sulfoxides
$-SO_2-$	sulfones
$-SO_2NH-$	sulfonamides
$-\overset{\vert}{\underset{\vert}{C}}-Me$	organometallic compounds
Oxidizable groups	**Compounds**
$A-\overset{\vert}{\underset{\vert}{C}}-H$	poly(aromatic) hydrocarbons (A = aryl)
$-OH$	phenols
$-NH_2$	aromatic amines
$-CO-N<$	amides
Groups reacting with mercury ions	**Compounds**
$-SH$	thiols
$-N-C(=S)S^-$	dithiocarbamates
$-NH-C(=S)-NH-$	thioureas, thiobarbiturates
$-C(=S)NH_2$	thioamides
$-NH-C(=O)-NH-$	derivatives of barbituric acid and of uracil

Figure 42. Potential ranges for the polarographic and voltametric half-wave and peak potentials of organic compounds

The *nitroso group* is generally more easily reducible than the nitro group. *N*-Nitrosamines, e.g., *N*-nitroso-*N*-methylaniline in blood, serum, or albumin, are determined in the µg/kg range by DPP [80]. The polarographic and voltammetric behavior of the nitrosamines, quinones, steroid hormones, and imidazoles is of interest, particularly in connection with cancer research [25].

Knowledge about the bio-transformation of *drugs* and their excretion is important pharmacologically. Numerous methods for the polarographic and voltammetric determination of pharmaceuticals and their metabolites have been developed for the assessment of such relationships. The determination is generally preceded by separation from the matrix by liquid – liquid extraction with diethyl ether or ethyl acetate.

1,4-Diazepines are determined polarographically via their azomethine groups. In addition to flurazepam, further representatives of this class of pharmaceutically active agents can be determined polarographically. These include diazepam, chlordiazepoxide, bromazepam, lorazepam, and chlorazepam; the limits of determination with DPP are in the µg/L range [4], [5].

Organic compounds with oxidizable functional groups (see Table 3) are mostly determined, after separation by liquid (column) chromatography or by high-performance liquid chromatography, with the aid of a voltammetric (amperometric) detector (→ Liquid Chromatography). These compounds, which can be determined in liquid and solid biological samples, in foods, or in aquatic environmental samples, include catecholamines, sulfonamides, phenothiazines, dopamines, estrogens and other hormones, tocopherols, and various groups of agricultural pesticides. Liquid – liquid extraction or solid phase extraction are also used for sample preparation; the determinations are carried out

Figure 43. Polarographic determination of NTA and EDTA according to DIN 38 413 Part 5, standard additions method
a) Residual current; b) After Bi^{3+} addition; c) First addition of Bi-NTA/EDTA solution; d) Second addition of Bi-NTA/EDTA solution

in the ng/L range (→ Liquid Chromatography, Chap. 8.1.).

Polarography and voltammetry are of importance in the *analysis of organometallic* compounds in environmental samples. In contrast to spectroscopic methods which only give information on the total metal contents in a sample, the voltammetric techniques are capable of characterizing and determining the various forms of those compounds as they exist in the sample (speciation).

Representative of the organometallic compounds are the R – Me – compounds where Me = As, Hg, P, Pb, Sb, Se, Sn, Te, and Ti; the peak potentials are listed in [30].

Organomercury compounds of the type RHgX generally are reduced in two steps according to the mechanism.

Likewise organo-arsenic, antimony, and tin compounds either singly or in admixture can be determined in the µg range by polarography and particularly mono-, di-, and tributyltin in the ng range, based on solid phase extraction and adsorptive cathodic stripping voltammetry [81].

The polarographic or voltammetric determination of organic compounds of biological, pharmaceutical, or environmental significance have been summarized [27–29].

In Chapter 2 the basics of calorimetry are presented. After the introduction of static and dynamic methods to measure heats or heat flow rates, different types of calorimeters are described, both of classical and of modern design. A section on applications of calorimetry in science and technology follows, where some essential fields such as determination of thermodynamic functions and safety studies are presented in more detail.

1. Thermal Analysis

1.1. General Introduction

1.1.1. Definitions

Thermal analysis (TA) has been defined as "a group of techniques in which a physical property of a substance and/or its reaction products is measured as a function of temperature while

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b06_001.pub2

the substance is subjected to a controlled temperature programme" [1]. The formal definition is usually extended to include isothermal studies, in which the property of interest is measured as a function of time.

The definition is a broad one, and covers many methods that are not considered to fall within the field of thermal analysis as it is usually understood. The present chapter will be restricted to major techniques. Since all materials respond to heat in some way, TA has been applied to almost every field of science, with a strong emphasis on solving problems in materials science and engineering, as well as fundamental chemical investigations. TA is applicable whenever the primary interest is in determining the effect of heat upon a material, but the techniques can also be used as a means of probing a system to obtain other types of information, such as composition.

The aim of this chapter is to give an overview of the main TA methods and their applications, with sufficient references to provide reader access to more detailed information. The following list summarizes properties subject to investigation and the corresponding thermal analysis techniques:

Mass	Thermogravimetry (TG)
Temperature	Differential thermal analysis (DTA)
Enthalpy	Differential scanning calorimetry (DSC)
Evolved gas	Evolved gas analysis (EGA)
Physical dimensions	Thermodilatometry (TD)
Mechanical properties	Thermomechanical analysis (TMA)
	Dynamic mechanical analysis (DMA)
Optical properties	Thermoptometry
Electrical properties	Thermoelectrometry
Magnetic properties	Thermomagnetometry

1.1.2. Sources of Information

Two journals (the *Journal of Thermal Analysis and Calorimetry* and *Thermochimica Acta*) devote their contents entirely to TA; the *Proceedings* of the (now) four-yearly Conferences of the International Confederation for Thermal Analysis and Calorimetry (ICTAC) constitute an excellent additional source of research papers. Specific information regarding *Proceedings* volumes for the nine ICTAC Conferences between 1965 and 1991 is available in [1]. The most complete listing of worldwide TA literature is also found in the ICTAC handbook [1], which in addition gives addresses for national TA societies and important equipment suppliers. The most useful textbooks include [2 – 5].

There is a wealth of information available on the Internet; see, for example,
http://www.users.globalnet.co.uk/∼dmprice/-ta/links/index.htm

1.2. Thermogravimetry

1.2.1. Introduction

Thermogravimetry (TG) is used to measure variations in mass as a function of temperature (or time). Processes amenable to study in this way are listed in Table 1. TG is one of the most powerful TA techniques from the standpoint of quantitative data, and for this reason it is often employed in combination with other measurements.

Table 1. Processes that can be studied by thermogravimetry

Process	Weight gain	Weight loss
Ad- or absorption	*	
Desorption		*
Dehydration/desolvation		*
Sublimation		*
Vaporization		*
Decomposition		*
Solid – solid reactions		*
Solid – gas reactions	*	*

1.2.2. Instrumentation

The instrument used is a *thermobalance*. The schematic diagram in Figure 1 presents the main components of a typical modern unit. Component details vary according to the design, and choice of a particular instrument is usually dictated by requirements of the problem under investigation (temperature range, sensitivity, etc.). The balance mechanism itself is usually of the null-deflection type to ensure that the sample's position in the furnace will not change. The balance transmits a continuous measure of the mass of the sample to an appropriate recording system, which is very often a computer. The resulting plot of mass vs. temperature or time is called a *TG curve*. Balance sensitivity is usually

of the order of one microgram, with a total capacity of as much as a few hundred milligrams. Furnaces are available that operate from subambient (e.g., −125 °C) or room temperature up to as high as 2400 °C. A furnace programmer normally supports a wide range of heating and cooling rates, often in combination, as well as precise isothermal control. The programming functions themselves are increasingly being assumed by computers. Most applications involve heating rates of 5 – 20 K/min, but the ability to heat a sample as rapidly as 1000 K/min can be useful in the simulation of certain industrial processes, for example, or in flammability studies. Special control methods, grouped under the term *controlled-rate thermal analysis* (CRTA), are receiving increasing attention [6], and offer advantages in resolving overlapping processes and in kinetic studies.

Figure 1. Schematic diagram of a thermobalance
a) Sample; b) Sample temperature sensor; c) Furnace temperature sensor; d) Furnace; e) Recorder or computer, logging sample mass, temperature, and time; f) Balance controller; g) Recording microbalance; h) Gas; i) Furnace temperature programmer
The computer may also control the furnace programmer

The quality of the furnace atmosphere deserves careful attention. Most commercial thermobalances operate at atmospheric pressure. Vacuum and high-pressure studies normally require specialized equipment, either commercial or home-made, as do experiments with corrosive gases [7]. The ability to establish an inert (oxygen-free) atmosphere is useful, as is the potential for rapidly changing the nature of the atmosphere.

The mode of assembly of the components varies; for example, the furnace might be above, below, or in line with the balance. Sample containers also vary widely in design; cylindrical pans are common, typically 5 – 8 mm in diameter and 2 – 10 mm high, though flat plates and semisealed containers may be used to investigate the effects of atmospheric access to a sample. Compatibility between the construction materials and the system under investigation must be carefully considered. Materials commonly available include aluminum, platinum, alumina, and silica. Temperature indication is normally provided by a thermocouple located near the sample container. Because of inevitable thermal gradients within the apparatus, an indicated temperature can never be taken as an accurate reflection of the temperature of the sample. Reproducible location of the thermocouple is vital; recommended calibration procedures have been described in [8]. Only in simultaneous TG – DTA instruments is direct measurement of the temperature possible.

1.2.3. Factors Affecting a TG Curve

Wendlandt [2] has listed 13 factors that directly affect a TG curve, both sample- and instrument-related, some of which are interactive. The primary factors are heating rate and sample size, an increase in either of which tends to increase the temperature at which sample decomposition occurs, and to decrease the resolution between successive mass losses. The particle size of the sample, the way in which it is packed, the crucible shape, and the gas flow rate also affect the progress of a thermal reaction. Careful attention to consistency in experimental details normally results in good repeatability. On the other hand, studying the effect of deliberate alterations in such factors as heating rate can provide valuable insights into the nature of observed reactions. All these considerations are equally applicable to other techniques as well, including DTA (Section 1.3).

1.2.4. Applications

TG has been applied extensively to the study of analytical precipitates for gravimetric analysis [9]. One example is calcium oxalate, as illustrated in Figure 2. Information such as extent of hydration, appropriate drying conditions, stability ranges for intermediate products, and reac-

tion mechanisms can all be deduced from appropriate TG curves. Figure 2 also includes the first derivative of the TG curve, termed the *DTG curve*, which is capable of revealing fine details more clearly.

Figure 2. TG (A) and DTG (B) curves for calcium oxalate monohydrate
Sample mass 30 mg, heating rate 20 K/min, argon atmosphere

Figure 3. TG curve (A) illustrating a programmed-temperature method for the proximate analysis of coal, where the line B defines the temperature program
a) Moisture; b) Volatiles; c) Fixed carbon; d) Ash; e) Point at which the atmosphere was changed to air

A TG method has also been devised for the proximate analysis of coal, permitting four samples per hour to be analyzed with results of the same precision and accuracy as BS and ASTM methods [10]. A typical curve is shown in Figure 3. The approach taken here can be generalized to the compositional analysis of many materials [11]. TG also facilitates comparisons of the relative stabilities of polymers (Fig. 4). An analysis of curves prepared at different heating rates makes it possible to extract kinetic data for estimating the service lifetimes of such materials. In another coal-related application, an empirical correlation has been established between characteristic temperatures obtained from DTG curves of coals examined under air and the performance of the same coals in steam-raising plants [12], permitting the rapid assessment of new fuels (Fig. 5). The simulation of industrial processes, particularly heterogeneous catalysis, is another important area of application.

1.3. Differential Thermal Analysis and Differential Scanning Calorimetry

1.3.1. Introduction

Both differential thermal analysis (DTA) and differential scanning calorimetry (DSC) are concerned with the measurement of energy changes, and as such are applicable in principle to a wider range of processes than TG. From a practical standpoint DSC may be regarded as the method from which quantitative data are most easily obtained. The use of DSC to determine absolute thermodynamic quantities is discussed in Sections 2.3.2 and 2.4.1. Types of processes amenable to study by these methods are summarized in Table 2.

Table 2. Processes that can be studied by DTA/DSC

Process	Exothermic	Endothermic

Ts, sample temperature; Tr, reference temperature; $\Delta T = T\text{s} - T\text{r}$

1.3.2. Instrumentation

Figure 6 shows the components of a typical DTA apparatus. The sample and an inert reference material (commonly alumina) are subjected to a common temperature program while the temperature difference between the two is monitored. In an ideally designed instrument, the temperature difference ΔT remains approximately constant if no reaction is taking place in the sample. When an endothermic process such as melting occurs, the sample temperature T_s lags behind that of the reference T_r; $\Delta T = T_\mathrm{s} - T_\mathrm{r}$ is thus negative, so a (negative) peak is produced on the corresponding *DTA curve*, which is a record of ΔT against either temperature or time (Fig. 7). Exothermic processes lead to peaks in the opposite direction. The peak *area* is related to both the energy change and the sample size according to the relationship

$$\Delta H \cdot m = K \int \Delta T \cdot \mathrm{d}t$$

where m is the sample mass, and ΔH is the enthalpy of reaction. The proportionality constant K is temperature-dependent, and with classical DTA it is also influenced by thermal properties of the sample and container. Certain apparatus designs minimize these influences, so that once the characteristics of $K = f\ (T)$ have been determined the ΔT signal can be conditioned (electronically or digitally) to give an output signal calibrated directly in power units; i.e., the sensitivity is nominally independent of temperature. This is the principle underlying heat-flux DSC. For a more complete description of this technique, as well as power-compensated DSC, see Section 2.3.2. A wide variety of commercial devices covers the temperature range from ca. −150 – 2500 °C, but high-temperature instruments are less sensitive than low-temperature designs due to constraints imposed by thermocouple technology. DSC instruments are usually limited to a maximum temperature of 700 °C, though heat-flux DSC has been extended to 1400 °C. DTA head designs vary enormously, but most accommodate samples in the range 5 – 200 mg in metal or ceramic containers. The thermocouples usually take the form of beads that fit into recesses in the containers, or plates upon

which the containers rest. Nowadays the thermocouple is never actually placed in the sample, in contrast to the "classical" arrangement shown in Figure 6.

Figure 7. Typical DTA curve for the melting of a pure material

1.3.3. Applications

DSC is used extensively in polymer science [13] (→ Plastics, Properties and Testing). A generalized DSC curve for a polymer is shown in Figure 8. Most polymers display a *glass transition*, in the course of which the material passes from a glassy to a rubbery state with a simultaneous increase in specific heat capacity (→ Plastics, Properties and Testing). Glass-transition temperature measurements are used for material characterization and comparison, often providing information about such factors as thermal history, crystallinity, extent of cure, and plasticizer content of a polymer. Amorphous polymers usually exhibit a crystallization exotherm, and thermosetting polymers a curing exotherm, both of which can be analyzed kinetically to establish the thermal treatment required to obtain desired properties in a particular product. The melting endotherm is a measure of the extent of crystallinity, an important parameter related to mechanical properties. The temperature at which exothermic degradation begins under an oxidizing atmosphere is used to compare oxidative stabilities of different polymers or different stabilizers. Discrimination can be improved by isothermal measurements, in which the material under investigation is heated initially in an inert gas, after which the atmosphere is changed to air or oxygen and the time lapse prior to exothermic deflection is measured. The same approach is applicable to studies of oils, greases, fats, etc., though high-pressure cells may be necessary to prevent volatilization.

Figure 8. Generalized DSC curve for a polymer
a) Glass transition; b) Crystallization; c) Melting
The subsequent reactions may be endothermic or exothermic

Figure 9. DTA curve for a partially converted high-alumina cement concrete from a test drilling
Degree of conversion $=100\ y/(x + y)$

The particular temperatures at which peaks are observed can be used for the identification of components in a mixture, and the size of a particular peak can be used for quantitative evaluation. Examples include the determination of quartz in clays and analysis of the constituents of polymer blends, both of which would be difficult to achieve by other means. DTA has been used to determine the presence and degree of conversion of high-alumina cement concrete (HAC), a material subject to severe loss of strength under certain atmospheric conditions due to solid-state

reactions in the cement matrix. Figure 9 shows a DTA curve for partially converted HAC together with the way the data are used for a conversion measurement.

An analysis of the shape of the fusion peak from a relatively pure material (e.g., a pharmaceutical agent) can, with certain restrictions, lead to an estimate of purity [14]. Figure 10 shows an idealized melting curve for an impure material. By calculating the fraction (F) of material melted at a series of temperatures, and applying several simplifying assumptions, the mole fraction of an impurity can be calculated from the expression:

$$T_s = T_0 - \frac{RT_0^2 X_2}{\Delta H_f} \cdot \frac{1}{F}$$

where T_s = sample temperature, T_0 = melting point of the pure material, R = gas constant, X_2 = mole fraction of impurity, ΔH_f = enthalpyof fusion, and F = the fraction melted at temperature T_s. The calculations are readily performed by commercial software.

Figure 10. Generalized DSC curve for the melting of an impure material
Fraction melted at temperature Tx = (area ABE)/(area ADC)

DTA curves can be used to construct phase diagrams for mixtures. Measurement of a single point on the phase diagram may be sufficient for quality-control purposes. Figure 11 shows the DTA curve for a nickel-based superalloy, where the solvus temperature (the temperature corresponding to complete solution of one solid phase in another) of the γ' phase characterizes the heat treatment to which the alloy has been subjected.

Solid – solid reactions have also been successfully studied by these techniques, as have decompositions of high explosives. The applicability of DTA/DSC to very small samples is of obvious value here. Similarly, preliminary screening of potentially hazardous reaction mixtures is conveniently carried out in this way as a guide to the likelihood of exothermic reaction, the corresponding temperature range and magnitude, and possible effects of pressure and atmospheric conditions (see also Section 2.4.5).

Figure 11. DTA curve for a nickel-based superalloy

1.3.4. Modulated-Temperature DSC (MT-DSC)

MT-DSC is an important development (see also Section 2.2.3) which offers significant advantages in the quality of results and gives additional information, particularly for polymers [15]. A sinusoidal modulation is superimposed on the normally linear temperature ramp, and the resulting signals are analyzed by a Fourier Transform technique. This allows the separation of "reversing" and "nonreversing" thermal events and simplifies the analysis of overlapping transitions such as those often found in the glass transition region. Other benefits include the ability to measure heat capacity changes pseudo-isothermally, as in, e.g., curing systems, and improved signal-to-noise ratio and baseline linearity.

1.4. Simultaneous Techniques

1.4.1. Introduction

TG or DTA/DSC alone rarely gives sufficient information to permit a complete interpretation

of the reactions in a particular system; results must usually be supplemented by other thermal methods and/or general analytical data. Alternative thermal methods are best applied simultaneously, leading, for example, to TG and DTA information from the same sample under identical experimental conditions. This avoids ambiguity caused by material inhomogeneity, but also problems attributable to different experimental conditions with different instruments, which sometimes markedly affects the correspondence between TG and DTA curves. Other advantages include: (1) indication of the thermal stability of materials examined by DTA, which in turn makes it possible to correct measured heats of reaction for partially decomposed samples; (2) accurate temperature measurement in TG work, which is vital in kinetic studies; and (3) the detection of unsuspected transitions in a condensed phase, which may help explain puzzling features of the corresponding TG curve.

Figure 12. Simultaneous TG – DSC curves for an uncured polyimide resin
a) Glass transition; b) Melting; c) Curing; d) Degradation
10 mg sample heated at 10 °C min^{-1} in argon

The range of simultaneous techniques has been reviewed by Paulik [16]. TG – DTA and TG – DSC are the commonest simultaneous methods, followed by evolved gas analysis (Section 1.5).

1.4.2. Applications

TG – DSC curves showing the curing and decomposition of a polyimide resin are presented in Figure 12. Following a glass transition (a) and subsequent fusion of the material at ca. 120 °C (b), which are detected by DSC, the TG curve reveals the initial stages of an exothermic curing reaction (c) that occurs with a 7 % mass loss. Endothermic decomposition of this resin does not take place until ca. 430 °C, as shown again by TG (d), a finding that permitted assignment of the appropriate baseline for measuring the heat of curing.

1.5. Evolved Gas Analysis

Evolved gas analysis (EGA) measures the nature and/or quantity of volatile products released on heating. In practice it is often performed simultaneously with TG or TG – DTA, and is particularly useful in furnishing direct chemical information to augment the physical measurements of TG or DTA. Additional advantages that have emerged include specificity – a single decomposition can be followed against a background of concurrent processes – and sensitivity, which can be far greater than with TG alone [17, 18].

Instrumentation. Almost every imaginable type of gas detector or analyzer has been utilized in EGA, including hygrometers, nondispersive infrared analyzers, and gas chromatographs. Absorption of the products into solution permits analysis by coulometry, colorimetry, ion selective electrode measurements, or titrimetry. The most important analyzers are Fourier transform infrared (FTIR) spectrometers and, preeminently, mass spectrometers [19]. The two latter methods can be used to record spectra repetitively, thereby producing a time-dependent record of the composition of the gas phase, from which EGA curves can be constructed for selected species.

Applications. Simultaneous TG – MS curves for a brick clay are shown in Figure 13, which simulates a set of firing conditions [20]. After an initial loss of moisture, combustion of organic matter at ca. 300 °C gives characteristic peaks for CO_2, H_2O, and SO_2. More SO_2 results from the oxidation of iron sulfides. Clay dehydroxylation occurs in the range 350 – 600 °C, and calcite dissociates to give the CO_2 peak observed at higher temperatures. EGA is of great value in the interpretation of complex TG and DTA curves.

Figure 13. Simultaneous TG – MS curves for a brick clay

Evolution of a) Water (M, 18); b) Carbon dioxide (M, 44); c) Sulfur dioxide (M, 64)
40 mg sample heated at 15 °C min^{-1} in air

In another example (Fig. 14), the evolution of benzene from two samples of PVC, one containing a smoke retardant, was compared quantitatively by injecting known amounts of benzene into the purge gas stream before and after the experiments, thereby providing a standard for estimating the amount of benzene produced by the polymer [20]. The smoke retardant was found in this case to reduce benzene evolution by a factor of ca. 20.

1.6. Mechanical Methods

This section covers a family of techniques leading to dimensional or mechanical data for a material as a function of temperature or time. For a succinct review of the application areas see [22].

Thermodilatometry (TD) measures dimensional changes as a function of temperature in materials subject to negligible loads. A probe, which is held in light contact with the heated sample, is connected to a sensitive position sensor, usually a linear variable differential transformer (LVDT). In addition to providing expansion coefficients the technique can also indicate phase changes, sintering, and chemical reactions. Major application areas include metallurgy and ceramics.

Figure 14. Simultaneous TG – MS curves showing the evolution of benzene (M_r, 78)
A) TG curve; B) MS curve
a) PVC without a smoke retardant; b) PVC with a smoke retardant (4 % MoO_3)
15 mg samples heated at 10 °C min^{-1} in argon

Thermomechanical Analysis. The equipment used in thermomechanical analysis (TMA) is similar in principle to that for TD, but provision is made for applying various types of load to the specimen, so that penetration, extension, and flexure can be measured. This approach to analyzing such modes of deformation is illustrated schematically in Figure 15. The technique finds most use in polymer studies, as in the determination of glass-transition and softening temperatures for thin films and shrinkage characteristics of fibers.

Figure 15. Modes of deformation subject to examination by TMA
A) Penetration; B) Extension; C) Flexure
a) Sample; b) Probe; c) Clamps; d) Load

Dynamic Mechanical Analysis. Polymers exhibit both elastic and viscous behavior under stress. In dynamic mechanical analysis (DMA) a sinusoidally modulated stress, often flexural (though measurement is also possible under tensile, compressive, shear, or torsional conditions) is applied to a specimen of material maintained under a specified temperature regime. Displacement transducers measure strain induced in-phase with the stress, as well as strain that lags behind. The former gives a measure of the sample's modulus, or stiffness, and the latter reflects damping characteristics. Like most other thermoanalytical techniques, DMA can be used to generate quantitative physical data, but it is also invoked in a comparative sense: to monitor the effects of additives, for example, or in quality control. It is particularly well suited to the examination of engineering composites, since gelation and curing behavior is sometimes more easily followed by DMA than by alternative techniques such as DSC.

1.7. Less Common Techniques

Thermoptometry. This group of techniques includes:

1) *Thermomicroscopy*, in which a material is observed under reflected, transmitted, or polarized transmitted light. The corresponding apparatus is referred to as a *hot stage*, which may also incorporate a DSC sensor for additional information.
2) *Thermophotometry*, in which the intensity of reflected or transmitted light is measured.
3) *Thermoluminescence*, which provides a measure of the intensity of light emitted by the material itself.

Electrical and Magnetic Techniques. Thermomagnetometry is used to study the magnetic properties of materials by revealing apparent weight changes that accompany phase transitions in the presence of an applied magnetic field, or variations in the amount of a magnetic substance.

Thermoelectrometry comprises methods for the measurement of resistance or capacitance during heating. Some equipment in this category provides remote probes for in situ monitoring of the curing of thermosets.

Microthermal analysis (μ-TA) enables a range of thermal methods to be applied to regions of a material only a few micrometers wide. They are based on the use of an atomic force microscope (AFM) with a heatable tip. Many materials are heterogeneous, and the microstructure can influence the material properties on the macroscale. After acquiring the conventional AFM topographic image, selected features can be subjected to DTA and TMA with the probe tip. The tip can also be used to pyrolyze the selected area, and the vapors are then analyzed by GC-MS [23].

2. Calorimetry

2.1. Introduction [24, 36 – 44]

Calorimetry in the broadest sense means the quantitative measurement of energy exchanged in the form of heat during a reaction of any type. By contrast, thermal analysis (Chap. 1) is concerned only with the measurement and recording of temperature-induced changes or temperature differences in dependence on time. Since all chemical reactions and many physical changes (e.g., deformation, phase transformations) are associated with the uptake or release of heat, the quantitative investigation of heat exchange is a

relatively simple and universal method for characterizing particular processes both in an overall sense and with respect to time.

Nevertheless, only in recent decades has calorimetry emerged from the laboratories of a few thermodynamicists and specialists to become a widespread, convenient analytical method. The development of commercial calorimeters since the 1950s has led to rapid dissemination and application of the method even beyond the bounds of universities.

The explanation of this phenomenon, as with many other apparatus-based developments, lies in the refinement in measurement techniques made possible by modern electronics. As a rule, heat cannot be measured directly, but must be determined instead on the basis of a temperature change in the system under investigation. Very accurate classical thermometers tend to be very slow measuring devices. Resistance thermometers and thermocouples respond much more rapidly, but they require electronic amplification, and amplifiers with the required precision have become available only in recent decades.

A further explanation for the increasing importance of calorimetry is the development of personal computers, which relieve the user of the often laborious task of evaluating the experimental results, thereby opening the way for the method to become a routine laboratory technique.

In the sections that follow, calorimetry and the present state of instrument development will be described in such a way as to reveal both the possibilities and the limits of the method. The scope of the chapter rules out exhaustive treatment of the subject, so the goal is rather to delineate the method and guide the interested reader to other relevant technical literature.

2.2. Methods of Calorimetry

As noted above, heat that is released or consumed by a process cannot be measured directly. Unlike material quantities such as amount of substance, which can be determined with a balance, or the volume of a liquid, which can be established with a liter measure, the quantity heat must be measured indirectly through its effect on a substance whose temperature it either raises or lowers. The fundamental equation for all of calorimetry describes the relationship between heat exchanged with a calorimeter substance and a corresponding temperature change:

$$\Delta Q = C\,(T) \cdot \Delta T \tag{1}$$

where ΔQ = exchanged heat (J), ΔT = observed temperature change (K), and C (T) = heat capacity (J/K).

For heats (and therefore temperature changes) that are not too large, the temperature change is directly proportional to the exchanged heat. The proportionality constant is the heat capacity of the calorimeter substance (previously referred to as the "water value"). However, if the temperature change exceeds a few Kelvin, the temperature dependence of heat capacity stands in the way of a linear relationship, and a knowledge of the temperature function of the particular heat capacity in question is required in order to determine heat on the basis of a measured temperature difference.

The relationship above leads directly to the standard calorimetric methods for determining the heat of a process: either temperature is held constant by appropriate compensation for the heat effect, and the required compensation power is measured, or a temperature change is determined and used to calculate a corresponding value for exchanged heat. A precondition for the latter approach is accurate knowledge of the heat capacity as well as the heat transport properties of the measurement system.

2.2.1. Compensation of the Thermal Effects

In the first method of heat measurement, temperature changes in the calorimeter substance are avoided by supplying or dissipating heat exactly equal in magnitude (but opposite in sign) to that associated with the process under investigation. As a rule, electrical energy is used to provide this compensation, either by introduction in the form of Joule's heat or dissipation through the Peltier effect. A combination approach is also possible, with an appropriate constant level of cooling and simultaneous controlled electrical heating. The requisite amount of compensation power can today be determined with a high degree of precision. It was once customary to invoke for compensation purposes "latent" heat derived from a phase change; in other words, heat released in

a process was measured by using it to melt a substance such as ice, with subsequent weighing of the resulting water and conversion of the data into energy units based on the known heat of fusion for ice.

The method of compensation is advantageous, since it permits measurements to be carried out under quasi-isothermal conditions, thereby avoiding heat loss from the calorimeter to the surroundings by heat transport processes. Furthermore, there is no need for a calibrated thermometer, only a sensor sufficiently sensitive to temperature changes to provide adequate control over the compensation power.

2.2.2. Measurement of a Temperature Difference

In this alternative method of heat measurement, which is also indirect, a measured temperature difference is used to calculate the amount of heat exchanged. A distinction can be made between temporal and spatial temperature-difference measurements. In *temporal* temperature-difference measurement the temperature of a calorimeter substance is measured before and after a process, and a corresponding heat is calculated on the basis of Equation (1) (which presupposes an accurate knowledge of the heat capacity). In the *spatial* method a temperature difference between two points within the calorimeter (or between the calorimeter substance and the surroundings) is the quantity of interest. The basis for interpretation in this case is from Fourier's law the equation for stationary heat conduction (Newton's law of cooling):

$$\Phi = \lambda(T) \cdot A \cdot \Delta T \cdot l^{-1} \tag{2}$$

where Φ = heat flow rate (W), $\lambda(T)$ = thermal conductivity (W m^{-1} K^{-1}), A = cross-sectional area (m^2), ΔT = temperature difference (K), and l = length (m).

From this expression it follows that the heat flow rate through a heat-conducting material is proportional to the corresponding temperature difference. If this temperature difference is recorded as a function of time, then for a given thermal conductivity one acquires a measure of the corresponding heat flow rate, which can be integrated to give a total heat. The technique itself is very simple, but the result will be correct only if the measured temperature difference accurately reflects the total heat flow rate and no heat is lost through undetected "heat leaks". Careful calibration and critical tests of the calorimeter are absolutely necessary if one hopes to obtain reliable results.

A fundamental disadvantage of the temperature-difference method is the fact that nonisothermal conditions prevail, so the precondition of a stationary state is fulfilled only approximately. The potential therefore exists for nonlinear phenomena in the heat-transport process, which might result in conditions outside the range of validity for Equation (2). Furthermore, with nonisothermal studies it is impossible to rule out completely the presence of undetected leaks. It must also be pointed out that in the case of nonisothermal studies the thermodynamic quantities of interest cannot be established according to the methods of reversible thermodynamics, at least not without further consideration. Strictly speaking, *irreversible thermodynamics* should be applied to nonisothermal calorimetry. Although the distinction is generally unimportant in normal calorimetric practice, it becomes essential in cases where time-dependent processes are involved with timescales which are comparable to those of the experiment, e.g., in the *temperature-modulated* mode of operation.

2.2.3. Temperature Modulation

The temperature-modulated mode of operation has been well known for many decades in calorimetry [45], but became well established only during the 1990s, when commercial DSC was modified this way [46]. The idea is to examine the behavior of the sample for periodic rather than for isothermal or constant-heating-rate temperature changes. In this way it is possible to obtain information on time-dependent processes within the sample that result in a time-dependent generalized (apparent) heat capacity function or, equivalently, in a complex frequency-dependent quantity. Similar complex quantities (electric susceptibility, Young's modulus) are known from other dynamic (dielectric or mechanical) measurement methods. They are widely used to investigate, say, relaxation processes of the material.

In calorimetry there are three established temperature modulation methods:

1) The sample is heated with a periodically changing heat flow from a electrical heater [47] or chopped light beam [48], and the temperature change of the sample (magnitude and phase shift) is measured as the response signal (*AC calorimetry*).
2) A thermal wave is sent into the sample from a metallic film that is evaporated onto its surface and which heats it periodically. The temperature change is measured by using the same metal film as a resistance thermometer. The third harmonic of the resulting temperature oscillations is proportional to the power input and depends on the product of the heat capacity and thermal conductivity of the sample in a characteristic way (*3ω method* [49]).
3) The sample (or furnace) temperature is controlled to follow a set course with superimposed periodical changes, and the heat flow rate is measured via the differential temperature between sample and reference (*temperature-modulated differential scanning calorimetry, TMDSC* [34, 50, 51]).

In all three cases, both the magnitude of the periodic part of the response signal and its phase shift with respect to the stimulating signal are measured, and this results in a complex quantity (temperature, heat flow rate, and heat capacity, respectively). As heat transport always requires time, the frequency of temperature modulation is normally limited to a maximum of 0.2 Hz to allow the heat to flow through the sample properly. For the 3ω method, however, frequencies of several kilohertz are possible because the heat source and the temperature probe are identical in this case. At the lower end, the frequency range is only limited by the noise threshold (sensitivity) of the sensors in question. As a rule only two decades are available. Consequently, only time-dependent processes with timescales within this window can be followed in the calorimeter.

For quasistatic conditions it follows from Equation (1) that:

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = \Phi = C_p \cdot \frac{\mathrm{d}T}{\mathrm{d}t} \tag{3}$$

where the real quantities heat flow rate Φ and temperature change (heating rate) are strictly proportional, with the real heat capacity C_p as proportionality factor. This implies an infinite propagation velocity of thermal waves and an infinitely fast excitation time of the vibrational states that characterize the (static) heat capacity of a sample. Both conditions are fulfilled for normal solids within the above-mentioned frequency range. In cases where processes are involved which need time, the heat flow rate and the temperature change are no longer proportional, and the process in question causes the heat flow to lag behind the temperature. This results formally in a time-dependent apparent heat capacity, and Equation (3) no longer holds; instead:

$$\Phi(t) = C_p(t) * \frac{\mathrm{d}T(t)}{\mathrm{d}t} \tag{4}$$

This appears very similar, but the operator * stands for the convolution product, which is an integral operator rather than a product [31, 52].

Equation (4) can be Fourier transformed and then reads:

$$\Phi(\omega) = C_p(\omega) \cdot \mathrm{Fourier}\left(\frac{\mathrm{d}T(t)}{\mathrm{d}t}\right) \tag{5}$$

The (complex) heat flow rate is given as a normal product of the complex heat capacity and the (complex) Fourier-transformed heating rate in the frequency domain. For a given $T(t)$ course (normally periodical with underlying constant heating rate), the complex heat capacity can be determined from the measured complex (magnitude and phase) heat flow rate function. The resulting C_p function is given either as real and imaginary part or as magnitude (absolute value) and phase. The two forms are mathematically equivalent. From the frequency dependence of these quantities the $C_p(t)$ behavior can be derived [31].

2.3. Calorimeters

There are many diverse types of calorimeters, differing with respect to measuring principle, mode of operation, and general construction. Measuring principles have been described in the preceding sections. In terms of mode of operation, two approaches can be distinguished: *static calorimeters*, in which the temperature remains constant or changes only in consequence of the heat of reaction, and *dynamic calorimeters*, in

which the temperature of the calorimeter substance is varied deliberately according to a prescribed program (usually linear with time).

With regard to construction, a distinction can be made between *single* and *differential calorimeters*. Twin design is characteristic of the latter: that is, all components are present in duplicate, and the two sets are arranged as identical as possible. The reaction under investigation takes place in one side of the device, while the other side contains an inert reference substance. The output signal represents the difference between signals originating in the sample and reference side. With such a difference signal all symmetrical effects cancel (e.g., the heat leaks to the surroundings).

2.3.1. Static Calorimeters

Considering first the static calorimeters, three types can be distinguished depending upon whether they are operated in an *isothermal, isoperibolic* (isoperibolic = uniform surroundings), or *adiabatic* manner.

2.3.1.1. Isothermal Calorimeters

In the *isothermal* mode of operation it is imperative that all thermal effects be somehow compensated. This is achieved either electrically or with the aid of a phase transition of some pure substance. Only phase-transition calorimeters can be regarded as strictly isothermal. In this case thermodynamics ensures that the temperature will remain precisely constant since it is controlled by a two-phase equilibrium of a pure substance. The most familiar example is the *ice calorimeter*, already in use by the end of the 18th century and developed further into a precision instrument about 100 years later by Bunsen (Fig. 16). The liquid – gas phase transition has also been used for thermal compensation purposes; in this case a heat of reaction can be determined accurately by measuring the volume of a vaporized gas.

Phase-transformation calorimeters are easy to construct, and for this reason they are not available commercially. Such a device permits very precise determination of the heat released during a process. An important drawback is the fact that the isothermal method is limited to the few fixed temperatures corresponding to phase transitions of suitable pure substances.

This disadvantage does not apply to an isothermal device based on electrical compensation. Nevertheless, calorimeters of the latter type operate only in a quasi-isothermal mode, since electronic control systems depend for their response upon small deviations from an established set point, and a certain amount of time is required for changing the prevailing temperature. The use of modern circuits and components ensures that errors from this source will be negligible, however. Electrical compensation makes it possible to follow both endothermic and exothermic processes. In both cases the compensation power is readily measured and recorded or processed further with a computer. Isothermal calorimeters are used quite generally for determining heats of mixing and solution. Commercial devices are available that also support the precise work required for multiphase thermodynamics. As a rule such calorimeters are of the single rather than the differential type.

Figure 16. Ice calorimeter (based on [53])
a) Sample holder; b) Calorimeter vessel; c) Capillary with mercury thread; d) Water; e) Ice; f) Ice – water mixture; g) Mercury

2.3.1.2. Isoperibolic Calorimeters

An *isoperibolic calorimeter* is distinguished by the fact that it is situated within a thermostated environment. As a result, the temperature of the surroundings is kept constant, as is the effect of

the surroundings on the calorimeter vessel. A well-defined thermal conduction path is maintained between the calorimeter vessel and its surroundings so that the temperature difference between the calorimeter vessel and the environment will be proportional to the heat flow rate. Temperature equilibration usually adheres to an exponential time function, and an integral taken over the entire course of this function is proportional to the heat of reaction. Such instruments often have exceptionally large time constants; that is, temperature equilibration occurs very slowly. Indeed, the greater the equilibration time, the more sensitive is the calorimeter. It is of course difficult with an exponential function to identify precisely the end point, so the integral over the measurement function and therefore the heat of interest are subject to corresponding degrees of uncertainty. The advantages lie in simplicity of construction and ease of producing a measurement signal (a straightforward temperature difference), which might for example be derived from a differential thermocouple and a simple set of amplifiers.

Figure 17. Tian – Calvet calorimeter
a, b) Heat conduction paths between measuring cells and block; c, d) Sample and reference containers; e) Isoperibolic block; f) Thermostatic jacket; g) Thermal insulation; h) Thermopiles

The best-known calorimeter of this type was developed by Tian and Calvet (Fig. 17). Here the defined heat-conduction path to the thermostated surroundings (a large aluminum block) consists of a large number of differential thermocouples coupled in series (thermopile). This arrangement permits optimum determination of the heat flow rate to the surroundings, and such an instrument can be very sensitive (*microcalorimeter*).

Figure 18. A classical mixing calorimeter (from Meyers Conversationslexikon, 1893)
a) Calorimeter vessel; b) Convection and radiation shield; c) Cover; d) Jacketing vessel (thermostated); e) Lifting mixer

If heat transport to the surroundings is restricted by suitable insulation, temperature equilibration becomes so slow that – with small corrections – temperature changes in the calorimeter substance alone can serve as the basis for determining the heat of a reaction. Calorimeters in this category include the classical *mixing calorimeter* (with heat exchange) in which the sample substance is brought into contact with a (usually) colder calorimeter substance, whereupon an intermediate "mixing temperature" is established (Fig. 18). Other examples of mixing calorimeters include the simpler types of *combustion calorimeters*, in which the calorimeter substance is water, and the *drop calorimeter* (see Fig. 24). The latter consists of a metal block whose temperature change subsequent to introduction of a sample of accurately known tem-

Figure 19. Flow calorimeter, with a chemical reaction occurring in the liquid
A, B reactants, A + B reaction product; a) Differential thermocouple

perature provides information about the sample's heat capacity. The category of isoperibolic calorimeters also includes *flow calorimeters*, in which two fluid media (usually liquids containing the reactants) are first brought to the temperature of the thermostated surroundings and then combined. The ensuing reaction causes a measurable temperature change, the extent of which is proportional to the heat of the reaction (Fig. 19).

2.3.1.3. Adiabatic Calorimeters

An *adiabatic calorimeter* is equipped with an electronic control system designed to ensure to the greatest extent possible that the surroundings of the calorimeter cell remain at all times at precisely the same temperature as the substance under examination. The object is to prevent virtually all heat transport to the surroundings, thereby making it possible to establish the total heat effect from the change in temperature of the calorimeter substance. Good adiabatic calorimeters are difficult to construct, and they are not available commercially. Nevertheless, precision instruments of this type permit quantities such as specific heat capacities, as well as associated anomalies, to be measured very accurately (Fig. 20). The method entails an extraordinary level of effort, and it is practiced only by specialists working in a few laboratories in the world [54].

Simpler *adiabatic calorimeters* are distributed commercially in the form of adiabatic mixing and combustion calorimeters. These constitute very satisfactory routine instruments, especially since the adiabatic mode of operation (which entails measurement of only a single temperature difference) facilitates automated data acquisition and interpretation.

2.3.2. Scanning Calorimeters

Scanning calorimeters are devices in which the sample temperature is deliberately changed during the course of an experiment according to a prescribed program. As a rule, heating or cooling of the sample is caused to occur linearly with time, and the heat flow rate required to accomplish the desired change is determined and output as a function of time or temperature. Any chemical or physical change in the sample at a particular temperature will manifest itself as a change in the heat flow rate, leading to a "peak" in the measurement curve whose area is proportional to the heat of the process (see also Section 1.3.2).

Such instruments have been on the market since the 1950s. Their great advantage is that

they permit heats of reaction and transformations of every type to be measured both rapidly and with reasonable precision. Heating rates usually fall in the range 5 – 20 K/min, so a measurement extending over 300 K can be completed within an hour, providing a reliable indication of all changes in the sample over this temperature range, including heats of reaction. The rapid development of calorimetry in recent years is due largely to the perfection of this type of calorimeter.

Figure 20. Construction of an adiabatic calorimeter (based on [55])
a) External radiation shield; b) Internal radiation shield; c) Adiabatic jacket; d) Calorimeter vessel; e) Sample suspension platform with resistance thermometer and heater; f) Electrical leads; g) Calorimeter suspension system

Scanning calorimeters are designed almost without exception as differential devices. With regard to the principle of measurement, two varieties can be distinguished: *differential-temperature* and *power-compensated calorimeters*. Although the two types rely upon very different approaches to determining heat flow rates with respect to the sample, and are therefore subject to different sources of error, they are marketed under the single heading *differential scanning calorimeter* (DSC). They can even be operated in *temperature-modulated* mode.

2.3.2.1. Differential-Temperature Scanning Calorimeters

In a differential-temperature scanning calorimeter the heat necessary for raising the sample temperature reaches the sample position via one well-defined heat conduction path (cf. Fig. 21). The measured signal is derived from a temperature difference generated along this path, which is proportional to the heat flow rate [see Eq. (2)]. This measuring and operating principle leads to the alternative designation *heat-flux calorimeter* for such a device. In order to minimize errors from heat leaks and other influences of the surroundings, calorimeters of this type are always based on a differential design, with full duplex construction. Many commercial models are available.

Figure 21. Operating principle of a temperature-difference scanning calorimeter (heat-flux calorimeter)
T_F furnace temperature, T_S sample temperature, T_R reference temperature, T_0 initial temperature, ΔT differential temperature $T_S - T_R$, β heating rate, t time

Any temperature difference between the sample and the reference is directly proportional to the corresponding differential heat flow rate, and so this is the quantity to be measured. The appropriate functional relationship follows directly from Equation (2):

$$\Phi = K(T) \cdot \Delta T \tag{6}$$

The heat flow rate of interest, Φ (in W), is proportional to the measured temperature difference ΔT (in K). Unfortunately, the proportionality constant K (the calibration factor for the calorimeter in K W^{-1}) is itself a function of the thermal conductivity of the sample [see Eq. (2)], and therefore temperature dependent. Moreover, temperature differences between the sample and the reference result in variable amounts of heat loss to the surroundings via inevitable heat leaks. Heat exchange with the environment also occurs via radiation and convection. Since the two transport processes are linked to temperature differences in a nonlinear way, the calibration factor in the presumably linear calorimeter equation necessarily depends on ΔT, which is the quantity to be measured. Consequently, the calibration factor depends upon such sample parameters as mass, thermal conductivity, and specific enthalpy difference [43], so heats measured with these instruments must realistically be assigned an uncertainty of about five percent unless considerable effort has been expended in calibration [56]. Repeatability of the results is generally many times better, but the user should not make the mistake of assuming an equally high level of certainty. Another source of systematic error may develop during the measurement if some reaction causes a change in the heat capacity and/or the extent of heat transfer to the sample holder. Both phenomena contribute to changes in the baseline, with the result that the course of the latter cannot be plotted accurately (Fig. 22). This in turn means that the area corresponding to the heat of reaction also cannot be determined exactly, leading to uncertainty in the associated heat [43]. Despite these restrictive comments, differential-temperature scanning calorimeters offer the advantages of a simple, transparent mode of operation and relatively low cost, and for this reason they account for a large share of the market. With appropriately critical supervision they are capable of fulfilling their assignment admirably. In 2002 a new type of heat-flux calorimeter with "Tzero® technique" [57] became commercially available. This DSC uses the power of modern computer technology to correct for some of the mentioned sources of error resulting in a higher certainty and better resolution of the measured curves and an excellent (almost zero) baseline.

2.3.2.2. Power-Compensated Scanning Calorimeters

Like differential-temperature devices, *power-compensated scanning calorimeters* always feature duplex construction, with sample and reference holders heated in such a way that at every instant the temperature of each corresponds almost exactly to a programmed set temperature. Any temperature differences that arise between sample and reference by reason of thermal events in the sample are compensated immediately by appropriate changes in the electrical heating (Fig. 23). The output signal is proportional to the instantaneous differential heat flow rate. Since temperature differences between sample and reference are essentially compensated at once, measurement errors due to undetected heat leaks can be largely avoided. Instruments of this type, the most widely distributed of which are manufactured by Perkin – Elmer instruments, require a very complicated electronic control system, and are therefore rather

expensive. The principal disadvantage lies in the fact that the electronic system is a black box for the average layman, thereby obscuring possible sources of error. These instruments also require that there be some deviation, albeit minimal, from the set temperature to guide the control circuit, so just as in the preceding case some systematic error must be anticipated (although certainly to a lesser degree), associated once again with temperature differences between sample and reference and nonlinear heat exchange. Accordingly, the level of systematic uncertainty for heats measured by power-compensated DSC can be estimated at 1 – 3 %.

Figure 23. Operating principle of a power-compensated differential scanning calorimeter (Perkin – Elmer)

2.3.2.3. Temperature-Modulated Scanning Calorimeters

Differential-temperature and power-compensated scanning calorimeters are now commercially available to run in the temperature modulated mode (TMDSC). In both cases the temperature is controlled to follow the normal (linear in time) course but with an additional periodical temperature change of particular amplitude and frequency. The measured heat flow rate function is the sum of the "underlying" part and the periodical part. The former can be extracted by calculating the "gliding average" integral over a period along the measured curve. It is identical to the curve that would be obtained in this DSC when the temperature modulation is switched off. The periodical part, on the other hand, is the difference of the measured and the underlying curves [31]. From the periodic part the complex C_p can be calculated by using Fourier analysis or other mathematical techniques. This enables time dependent-processes to be investigated in cases where their timescale falls within the frequency window of the TMDSC method [31].

For precise measurements it is necessary to correct (calibrate) the measured heat flow rate magnitude and phase shift for influences from the apparatus, as well as from the heat transport, which also is a time-dependent process and therefore influences the measured heat flow rate function [31, 58, 59].

2.3.3. Chip-Calorimeters

In the early 2000s a huge progress has been made in miniaturization of electronic equipment, in particular in the field of integrated circuits. It became more and more easy to produce "chips" with thin Si or SiN membranes as basis which can be used as micro- or nanocalorimeters. Such *chip-calorimeters* have on the one hand a very fast response time (in the milliseconds region) and open the possibility to measure very small samples (nanograms) at heating and cooling rates up to 5000 K/s [60] (for details see [61] and other articles in this special issue of *Thermochimica Acta*). This technology opens very new fields of research on thermodynamic behavior of small particles as well as membranes on the one hand and the detection of very small amounts of substances with the help of specific chemical reactions on the other hand. The latter can be a large step toward the development of an "artificial nose" which may serve as a sensor to detect, say, dangerous gases in the surroundings.

2.4. Applications of Calorimetry

Modern calorimeters permit relatively rapid and truly precise measurement of heat exchanges in a wide variety of reactions. Since heat evolution is proportional to the conversion (extent of reaction) in a chemical, physical, or biological reaction, calorimetric measurement constitutes one method for quantitative evaluation of the reaction itself. Measurement is possible not only of the total heat (and therefore the total conversion) of a reaction but also of the course of the reaction with respect to time. This opens the way to studies of kinetics, problems related to stability and safety, and other areas in which temperature and time-dependencies in a reaction play a part.

The sections that follow describe several possible applications of calorimetry, although these should be regarded only as illustrative, since the scope of the present article rules out any treatment that is even approximately exhaustive. No such limits apply to the reader's imagination, however, and any process that generates (or consumes) heat can in principle be followed with a calorimeter. Enzymatic and bacterial manufacturing processes have assumed increasing importance in industry, and interest in biocalorimetry is growing accordingly [62 – 64].

2.4.1. Determination of Thermodynamic Functions

Various *thermodynamic potential functions* (enthalpy, entropy, free energy, etc.) can be determined by integration on the basis of *specific heat capacities*. The accurate establishment of specific heat capacities at constant pressure, c_p, as a function of temperature is thus of fundamental importance. Different types of calorimeters are used for determinations of c_p depending upon accuracy requirements and the temperature range in question.

The most accurate results are obtained with adiabatic calorimeters, which are useful over a temperature range from fractions of a Kelvin to about 1000 K. These instruments permit specific heat capacities to be determined with very small uncertainties (<1 %). Nevertheless, such measurements are so complex that they are rarely applicable to normal laboratory practice in industry, especially given the lack of commercial instruments.

The standard approach to c_p measurement therefore relies on the less precise but more easily constructed and operated mixing calorimeters, in particular drop calorimeters (Fig. 24). A (mean) specific heat capacity is calculated in this case from the heat released when a sample of known temperature is introduced (dropped) into an isoperibolic calorimeter. Charging temperatures may exceed 2500 K. Determining the temperature dependence of c_p requires many individual measurements at various charging temperatures. The uncertainty in such measurements is usually 3 – 5 %.

Figure 24. High-temperature drop calorimeter (based on [66])
a) Sample; b) Heated corundum tube; c) Magnesia insulation; d) Cooling coils; e) Sample mounting device; f) Copper block; g) Hole for receiving sample; h) Resistance thermometer; i) Level of the thermostated oil bath

A truly elegant method for determining c_p at <1000 K takes advantage of a scanning calorimeter [43], preferably a power-compensated DSC. The procedure involves raising the temperature of a sample in the calorimeter at a defined rate (typically 10 K/min). The

same measurement is subsequently repeated, this time with empty crucibles. The difference between the two measurement curves provides a record of the heat flow rate into the sample, from which the specific heat capacity can be calculated. This method makes it possible conveniently to measure the $c_p(T)$ of a material over a temperature range of several hundred Kelvins within the course of a single day. However, it does demand a very high level of repeatability (baseline stability) for the DSC in question. In the case of differential-temperature (heat-flux) DSC – even with careful calibration – uncertainties of 5 – 10 % in the results must be anticipated. With power-compensated DSC the systematic uncertainties tend to be in the range of 3 – 5 %. Uncertainties in the calculated thermodynamic potential functions of interest are comparable.

The TMDSC enables another elegant possibility of c_p (magnitude) determination from the amplitude of the modulated part of the measured heat flow rate function both in the isothermal and scanning modes of operation. This method is especially advantageous in cases of noisy signals with low sample masses or low heating rates. Precise calibration of the heat flow rate amplitude is a prerequisite for obtaining reliable results [31, 59, 60].

However, a calorimeter operating dynamically always indicates a temperature that deviates to a greater or lesser extent from the true sample temperature, resulting in further uncertainty. It must in any case be borne in mind that potential functions determined on the basis of thermodynamic equilibrium, and thus defined statically, may differ from functions determined dynamically, since equilibrium conditions are not maintained in DSC, and in the case of a reaction even stationary conditions are lacking.

If time-dependent processes are involved, then the process is clearly outside the scope of classical thermodynamics. The time-dependent (apparent) heat capacity, measured with, say, TMDSC would lead to time-dependent potential functions which must be interpreted in terms of *irreversible thermodynamics*. In such cases, a nonzero imaginary part of the complex heat capacity exists which is linked to the entropy production of the process in question (for details see [44]). Thus, temperature-modulated calorimetry makes it possible to determine time-dependent (irreversible) thermodynamic quantities.

2.4.2. Determination of Heats of Mixing

For liquid systems consisting of several components, multiphase thermodynamics provides the theoretical background for computing phase diagrams from heats of mixing for the relevant components. Phase diagrams in turn are interesting not only to thermodynamicists; they are also of great importance in chemical process engineering practice.

The determination of heats of mixing is a classical field of investigation for calorimetry, one that at the required level of precision is today incomparably less laborious than previously. Enthalpies of mixing were formerly determined in some cases indirectly via vapor pressure measurements, but today they are measured directly in (quasi)isothermal or isoperibolic calorimeters. Recently also chip-calorimeters have been used for this purpose [65].

The art of conducting such an experiment successfully lies in rigorously excluding vaporization during the measurement, since specific heats of vaporization are orders of magnitude larger than the effects of mixing that are to be measured. As excess quantities (which characterize deviations from ideal behavior), heats of mixing are invariably small, and they must be determined with high precision in order to permit the construction of sufficiently precise phase diagrams. Isothermal calorimeters are therefore definitely to be preferred, since here the problem of incomplete determination of a heat of mixing – owing perhaps to undetected heat leaks – is less severe than with an isoperibolic instrument. Moreover, the isothermal heat of mixing is defined more precisely, and it lends itself more readily to mathematical treatment than in the case of parallel temperature changes.

Phase transitions in solid mixtures can be followed directly in a scanning calorimeter, since vapor pressures associated with the components are here so low that vaporization plays virtually no role and therefore does not interfere. Corresponding phase diagrams (i.e., liquidus – solidus curves) can be inferred from heat flow rate curves obtained by controlled heating and cooling of appropriate mixtures (cf. Section

1.3.3). Thermodynamically relevant quantities can in turn be determined indirectly by comparing measured phase diagrams with calculated diagrams.

2.4.3. Combustion Calorimetry

The determination of heats of combustion for fuels of all types is prescribed in detail by government regulation, since the "calorific value" or "heat content" of a particular coal, oil, or natural or manufactured gas determines its economic value. Combustion calorimeters or "bomb calorimeters" (usually operated adiabatically) are used for such measurements, whereby the sample is combusted in a "calorimetric bomb" (likewise standardized; cf. Fig. 25) in pure oxygen at $3 \cdot 10^6$ Pa to a defined set of end products. Methods of measurement and interpretation are also standardized, and they have been simplified to such an extent that the entire procedure can be automated.

Figure 25. Example of a calorimetric bomb for use in a combustion calorimeter
a) Pressure vessel; b) Screw cap; c) Sealing ring; d) Inlet valve; e) Outlet valve; f) Sample crucible with sample; g) Crucible holder; h) Heat shield

The same instruments are useful for determining heats of combustion for a wide variety of (usually organic) substances, from which standard enthalpies of formation can be determined. For these calorimetric methods errors in measurement are very small (< 1 ‰), with a level of precision that is also appropriate for analytical purposes (e.g., purity or composition checks on batches of chemicals). Combustion calorimetry is useful in biology as well. For example, in determinations of the nutrient content of leaves and fruits as a function of season and place based on appropriate heats of combustion.

Many combustion calorimeters are available commercially. Instruments utilizing water as the calorimeter substance generally operate adiabatically, thereby avoiding the somewhat complicated Regnault – Pfaundler procedure (cf. [41]) for determining and interpreting prior and subsequent temperature patterns. "Dry" combustion calorimeters that avoid the use of water or other liquids have also come onto the market.

2.4.4. Reaction Calorimetry

Every chemical process is associated with some type of heat effect. Accurate knowledge of heat released or consumed is of great importance in process engineering. Moreover, heat evolution is strictly coupled with the particular course of a reaction. If one is able to determine unambiguously the time dependence of the heat flow rate associated with a particular sample, one also gains access to the corresponding reaction rate law, which in turn opens the way to the reaction kinetics [43]. Knowledge of the appropriate kinetic parameters permits one to predict the course of the reaction under other sets of conditions, which is of great practical value. Heat of reaction determinations as well as kinetic studies are best carried out under isothermal (and isobaric) conditions, and for this reason it is advisable to select a (quasi)isothermal calorimeter with compensation for effects of the measurement process. One practical difficulty lies in the fact that reaction begins immediately after introduction of the sample at the appropriate temperature, even though the calorimeter itself is not yet at thermal equilibrium (and therefore not ready for use). One way out of this dilemma is to devise a system for bringing the components of the reaction together only after isothermicity

Figure 26. Operating principle of a reaction calorimeter (Contraves)

has been achieved. With liquids the challenge is not particularly great, since pumps and stirrers can ensure rapid (and thorough) mixing of the reactants at any desired time. The piercing of a membrane (or an ampoule) is also a common expedient. Another possibility is the use of a specially designed reaction calorimeter. With one device of this type the first reactant is present from the outset in a suitable glass or metallic vessel, to which a second reactant is added with mixing after stationary conditions have been established (Fig. 26). With the aid of electronic temperature control the reaction can then be carried out in any way desired: isothermally, adiabatically, or under the influence of some temperature program. Measurement of the relevant quantities, process control, and thermochemical data interpretation are all accomplished with the aid of a personal computer. A second type of special reaction calorimeter, suitable only for liquid components, is so constructed that each reactant is pumped in through its own system of tubing, with the streams uniting after temperature equilibration (Fig. 27). The ensuing reaction causes a temperature change, from which the corresponding heat of reaction can be calculated.

Transport and mixing of liquid or gaseous components is accomplished rather easily, but the situation is more complex for solid substances or mixtures. Here there is little hope of satisfactorily mixing the components inside a normal calorimeter, so one is forced to resort to a scanning calorimeter. The calorimeter is charged at a temperature below that at which the substances react, after which the temperature is increased linearly with time until reaction is complete. From a heat flow rate – time function acquired at a well-defined heating rate it is possible to establish both the heat of reaction and, if need be, kinetic parameters for the process. One prerequisite, however, is that the recorded function reproduces in an unbiased way the true heat production of the sample. This presents serious problems, since heat must in-

evitably flow from the point at which it is generated to the site of the temperature sensors before any measurement signal can appear. In the case of a fairly rapid chemical process, where the rate constant is comparable to the time constant of the calorimeter, the measurement signal from the recording device must be treated mathematically ("desmeared") [43] before it can be utilized for a kinetic analysis.

2.4.5. Safety Studies

Calorimetric methods applicable to safety studies are also concerned with clarifying the kinetic behavior of substances, but in this case from a safety engineering viewpoint.

The vast majority of chemical substances are endothermic materials; that is, they release heat when they decompose, and their decomposition is accelerated by heat. Chemical reaction kinetics teaches that any reaction is capable of proceeding at temperatures considerably lower than the temperature at which the maximum reaction rate is achieved. Usually, however, the reaction rate under these conditions is so low that the process is not apparent. The more unstable a substance, the lower is its decomposition temperature, and therefore the greater its decomposition rate at room temperature. In the event that heat evolved during storage – attributable to traces of reaction occurring under storage conditions – exceeds the level at which heat is emitted to the surroundings, then the decomposition rate may increase very rapidly, possibly to the point of an explosion.

Thorough knowledge of decomposition kinetics is therefore essential for ensuring safe storage and handling. The requisite information can, in principle, be gained through the methods described in Section 2.4.4, but it is often impossible to avoid an uncontrolled outcome and simultaneous destruction of the measuring system. This obviously rules out the use of expensive apparatus, which has led to the development of special safety calorimeters that are either inexpensive and disposable or designed to withstand the effects of violent reactions.

Simple arrangements of this type clearly preclude precision measurements, but they are entirely adequate from the specific viewpoint of assessing storage safety at particular temperatures or with particular types of packaging. The simplest example is an exceedingly primitive isoperibolic calorimeter consisting of a glass ampoule, either open or fitted with a pressure-tight closure, mounted together with a thermocouple inside a small furnace – a device that anyone can easily assemble and calibrate. More ambitious designs differ from standard calorimeters in that the sample holder (or measuring head) is incorporated into an autoclave of sufficient stability to permit studying the thermal behavior even of explosives. Included in this category are the so-called accelerating rate calorimeters (ARC), in which a sample is heated very slowly under quasiadiabatic conditions until the reaction intensifies by itself as a result of exothermic decomposition. The resulting temperature – time function can then be used to establish the corresponding heat effect and stability behavior.

1. Introduction

Wherever the properties of a solid surface are important, it is also important to have the means

Table 1. Surface-specific analytical techniques ∗ using particle excitation. The acronyms printed in bold belong to methods discussed in more details in this article.

to measure those properties. The surfaces of solids play an overriding part in a remarkably large number of processes, phenomena, and materials of technological importance. These include catalysis; corrosion, passivation, and rust; adhesion; tribology, friction, and wear; brittle fracture of metals and ceramics; microelectronics; composites; surface treatments of polymers and plastics; protective coatings; superconductors; and solid surface reactions of all types with gases, liquids, or other solids. The surfaces in question are not always external; processes occurring at inner surfaces such as interfaces and grain boundaries are often just as critical to the behavior of the material. In all the above cases, the nature of a process or of material behavior can be understood completely only if information about both surface composition (i.e., types of atoms present and their concentrations) and surface chemistry (i.e., chemical states of the atoms) is available. Occasionally, knowledge of the arrangement of surface atoms (i.e., the surface structure) is also necessary.

First of all, what is meant by a *solid surface*? Ideally the surface should be defined as the plane at which the solid terminates, that is, the last atom layer before the adjacent phase (vacuum, vapor, liquid, or another solid) begins. Unfortunately such a definition is impractical because the effect of termination extends into the solid beyond the outermost atom layer. Indeed, the current definition is based on that knowledge, and the surface is thus regarded as consisting of that number of atom layers over which the effect of termination of the solid decays until bulk properties are reached. In practice, this decay distance is on the order of 5 – 20 nm.

By a fortunate coincidence, the depth into the solid from which information is provided by the techniques described here matches the above definition of a surface almost exactly. These techniques are therefore *surface-specific*; in other words, their information comes only from that very shallow depth of a few atom layers. There are other techniques that can be *surface-sensitive*, in that they would normally be regarded as techniques for bulk analysis but have sufficient sensitivity for certain elements that they can be analyzed even if they are present only on the surface.

Why should surfaces be so important? The answer is twofold. First, because the properties of surface atoms are usually different from those of the same atoms in the bulk; second, because in any interaction of a solid with another phase, the surface atoms are the first to be encountered. Even at the surface of a *perfect single crystal* the surface atoms behave differently from those in the bulk simply because they do not have the same number of nearest neighbors; their electronic distributions are altered and hence their reactivity. Their structural arrangement is often

also different. When the surface of a *polycrystalline or glassy multielemental solid* is considered, such as that of an alloy or a chemical compound, the situation can be very complex. The processes of preparation or fabrication may produce a material whose surface composition is quite different from that of the bulk, in terms of both constituent and impurity elements. Subsequent treatments (e.g., thermal and chemical) will almost certainly change the surface composition to something different again. The surface is highly unlikely to be smooth, and roughness at both micro- and macrolevels may be present, leading to the likelihood that many surface atoms will be situated at corners and edges and on protuberances (i.e., in positions of increased reactivity). Surfaces exposed to the atmosphere, which include many of those of technological interest, will acquire a contaminant layer 1 – 2 atom layers thick, containing principally carbon and oxygen but also other impurities present in the local environment. Atmospheric exposure may also cause oxidation. Because of all these possibilities the surface region must be considered as a separate entity, effectively a separate quasi-two-dimensional phase overlaying the normal bulk phase. Analysis of the properties of such a quasi-phase necessitates the use of techniques in which the information provided originates only or largely within the phase (i.e., the surface-specific techniques described in this article).

Nearly all these techniques involve interrogation of the surface with a particle probe. The function of the probe is to excite surface atoms into states giving rise to emission of one or more of a variety of secondary particles such as electrons, photons, positive and secondary ions, and neutrals. Since the primary particles used in the probing beam may also be either electrons or photons, or ions or neutrals, many separate techniques are possible, each based on a different primary – secondary particle combination. Most of these possibilities have now been established, but in fact not all the resultant techniques are of general application, some because of the restricted or specialized nature of the information obtained and others because of difficult experimental requirements. In this article, therefore, most space is devoted to surface analytical techniques that are widely applied and readily available commercially, whereas much briefer descriptions are given of the many others whose use is less common but which – in appropriate circumstances, particularly in basic research – can provide vital information.

Because the various types of particle can appear in both primary excitation and secondary emission, most authors and reviewers have found it convenient to group the techniques in a matrix, in which the columns refer to the nature of the exciting particle and the rows to the nature of the emitted particle [1–9]. Such a matrix of techniques is given in Table 1, with the acronyms now accepted. The meanings of the acronyms, together with some of the alternatives that have appeared in the literature, are in Listing 1.

A few techniques, including one or two important ones, cannot be classified according to the nature of the exciting particle, since they do not employ primary particles but depend instead on the application either of heat or a high electric field. These techniques are listed in Table 2.

Listing 1. Meanings of surface analysis acronyms, and their alternatives, that appear in Tables 1 and 2.

1) Electron Excitation

AEAPS	Auger electron appearance potential spectroscopy
AES	Auger electron spectroscopy
BIS	Bremsstrahlung isochromat spectroscopy
CEELS	Core-electron energy loss spectroscopy (or ILS: ionization loss spectroscopy)
DAPS	Disappearance potential spectroscopy
EELS	Electron energy loss spectroscopy
ESD	Electron-stimulated desorption (or EID: electron-induced desorption)
ESDIAD	Electron-stimulated desorption ion angular distribution
HREELS	High-resolution electron energy loss spectroscopy (or LEELS: low-energy electron loss spectroscopy)
IPES	Inverse photoemission spectroscopy
LEED	Low-energy electron diffraction
RHEED	Reflection high-energy electron diffraction

SXAPS Soft X-ray appearance potential spectroscopy (or APS appearance potential spectroscopy)
SAM Scanning Auger microscopy

2) Ion Excitation

GDMS Glow discharge mass spectrometry
GD-OES Glow discharge optical emission spectroscopy
IAES Ion (excited) Auger electron spectroscopy
IBSCA Ion beam spectrochemical analysis (or SCANIIR: surface composition by analysis of neutral and ion impact radiation, or BLE: bombardment-induced light emission)
INS Ion neutralization spectroscopy
LEIS Low energy ion scattering (or ISS: ion scattering spectroscopy)
MQS Metastable quenching spectroscopy
RBS Rutherford backscattering spectroscopy (or HEIS: high-energy ion scattering)
SIMS Secondary-ion mass spectrometry (SSIMS: static secondary-ion mass spectrometry) (DSIMS: dynamic secondary-ion mass spectrometry)
SNMS Secondary neutral mass spectrometry

3) Photon Excitation

ELL Ellipsometry
RAIRS Reflection – absorption infrared spectroscopy (or IRRAS: infrared reflection – absorption spectroscopy) (or IRAS: infrared absorption spectroscopy) (or ERIRS: external reflection infrared spectroscopy)
SEIRA Surface-enhanced IR absorption spectroscopy
SERS Surface-enhanced Raman scattering
SHG Optical second harmonic generation
TXRF Total reflection X-ray fluorescence analysis
UPS Ultraviolet photoelectron spectroscopy
XPS X-ray photoelectron spectroscopy (or ESCA: electron spectroscopy for chemical analysis)

4) Neutral Excitation

FABMS Fast-atom bombardment mass spectrometry

5) Thermal Excitation

TDS Thermal desorption spectroscopy

6) High-Field Excitation

APFIM Atom probe field-ion microscopy
IETS Inelastic electron tunneling spectroscopy
POSAP Position-sensitive atom probe
STM Scanning tunneling microscopy
STS Scanning tunneling spectroscopy

7) Mechanical Force

AFM Atomic force microscopy

Table 2. Surface-specific analytical techniques ∗ using nonparticle excitation. The acronyms printed in bold belong to methods discussed in more detail in this article.

Detection	Excitation

2. Electron Detection

2.1. X-Ray Photoelectron Spectroscopy (XPS)

X-ray photoelectron spectroscopy is the most widely used surface analytical technique, and is therefore described here in more detail than any of the other techniques. At its inception by Siegbahn et al. [10] it was called ESCA (electron spectroscopy for chemical analysis), but the name ESCA is now considered too general, since many surface electron spectroscopies exist, and the name given to each one must be precise. Nevertheless, the name ESCA is still used in many places, particularly in industrial laboratories and

their publications. Briefly, the reasons for the popularity of XPS are the exceptional combination of compositional and chemical information that it provides, its ease of operation, and the ready availability of commercial equipment.

2.1.1. Principles

The surface to be analyzed is irradiated with soft X-ray photons. When a photon of energy $h\nu$ interacts with an electron in a level with binding energy E_{B} (E_{B} is the energy E_{K} of the K-shell in Figure 1), the entire photon energy is transferred to the electron, with the result that a photoelectron is ejected with kinetic energy

$$E_{\mathrm{kin}} = h\nu - E_{\mathrm{B}} - \Phi_S \tag{2.1}$$

where Φ_{S} is a small, almost constant, work-function term.

Clearly $h\nu$ must be greater than E_{B}. The ejected electron may come from a core level or from the occupied portion of the valence band, but in XPS most attention is focused on electrons in core levels. Since no two elements share the same set of electronic binding energies, measurement of the photoelectron kinetic energies provides an *elemental analysis*. In addition, Equation (2.1) indicates that any changes in E_{B} are reflected in E_{kin}, which means that changes in the chemical environment of an atom can be followed by monitoring changes in the photoelectron energies, leading to the provision of *chemical information*. XPS can analyze all elements in the periodic table except hydrogen and helium.

Although XPS is concerned principally with photoelectrons and their kinetic energies, ejection of electrons by other processes also occurs. An ejected photoelectron leaves behind a core hole in the atom. The sequence of events following the creation of the core hole is shown schematically in Figure 1 (right). In the example, the hole has been created in the K shell, giving rise to a photoelectron whose kinetic energy would be ($h\nu - E_{\mathrm{K}}$), and is filled by an electronic transition from the unresolved L_2 shell. The energy $E_{\mathrm{K}} - E_{\mathrm{L}_{23}}$ associated with the transition can then either be dissipated as a characteristic X-ray photon or given up to an electron in the same or a higher shell, also shown in this example as the L_{23} shell. The second of these possibilities is called the Auger process after its discoverer [11], and the resultant ejected electron is called an Auger electron and has an energy given by

$$E_{\mathrm{kin}}\,(\mathrm{KL_1L_{23}}) = E_{\mathrm{K}} - E_{\mathrm{L}_1} - E_{\mathrm{L}_{23}} - f\,(\mathrm{L_1L_{23}}) + R - \Phi_S \tag{2.2}$$

where $f(\mathrm{L_1L_{23}})$ is the interaction energy between the holes in the L_1 and L_{23} shells, and R is the sum of the intra- and extra-atomic relaxation energies. X-ray photon emission (i.e., X-ray fluorescence) and Auger electron emission are obviously competing processes, but for the shallow core levels involved in XPS and AES the Auger process is far more likely.

Thus, in all X-ray photoelectron spectra, features appear due to both photoemission and Auger emission. In XPS, the Auger features can be useful but are not central to the technique, whereas in AES (see Chap. 2.3), Equation (2.2) forms the basis of the technique.

At this point the nomenclature used in XPS and AES should be explained. In XPS the *spectroscopic notation* is used, and in AES the *X-ray notation*. The two are equivalent, the different usages having arisen for historical reasons, but the differentiation is a convenient one. They are both based on the so-called j–j coupling scheme describing the orbital motion of an electron around an atomic nucleus, in which the total angular momentum of an electron is found by summing vectorially the individual electron spin and angular momenta. Thus if l is the electronic angular momentum quantum number and s the electronic spin momentum quantum number, the total angular momentum for each electron is given by $j = l + s$. Since l can take the values 0, 1, 2, 3, 4, ... and $s = \pm\frac{1}{2}$, clearly $j = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}$, etc. The principal quantum number n can take values 1, 2, 3, 4, ... In *spectroscopic notation*, states with $l = 0$, 1, 2, 3, ... are designated s, p, d, f, ..., respectively, and the letter is preceded by the number n; the j values are then appended as suffixes. Therefore, one obtains 1s, 2s, $2\mathrm{p}_{1/2}$, $2\mathrm{p}_{3/2}$, 3s, $3\mathrm{p}_{1/2}$, $3\mathrm{p}_{3/2}$, etc.

In *X-ray notation*, states with $n = 1, 2, 3, 4, \ldots$ are designated K, L, M, N, ..., respectively, and states with various combinations of $l = 0$, 1, 2, 3, ... and $j = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}$, are appended as the suffixes 1, 2, 3, 4, ... In this way one arrives at K,

Figure 1. Schematic diagram of electron emission processes in solids. Left: Auger process; Right: photoelectron process. Electrons involved in the emission processes are indicated by open circles.

L_1, L_2, L_3, M_1, M_2, M_3, etc. The equivalence of the two notations is set out in Table 3.

Table 3. Spectroscopic and X-ray notations

Quantum numbers			Spectroscopic	X-ray	X-ray
n	l	j	state	suffix	state
1	0	1/2	1s	1	K
2	0	1/2	2s	1	L_1
2	1	1/2	$2p_{1/2}$	2	L_2
2	1	3/2	$2p_{3/2}$	3	L_3
3	0	1/2	3s	1	M_1
3	1	1/2	$3p_{1/2}$	2	M_2
3	1	3/2	$3p_{3/2}$	3	M_3
3	2	3/2	$3d_{3/2}$	4	M_4
3	2	5/2	$3d_{5/2}$	5	M_5
	etc.		etc.	etc.	etc.

In X-ray notation the Auger transition shown in Figure 1 would therefore be labeled KL_2L_3. In this coupling scheme, six Auger transitions would be possible in the KLL series. Obviously, many other series are possible (e.g., KLM, LMM, MNN). These are discussed more fully in Section 2.3.

The reasons why techniques such as XPS and AES, which involve measurement of the energies of ejected electrons, are so surface-specific, should be examined. An electron with kinetic energy E moving through a solid matrix M has a probability of traveling a certain distance before losing all or part of its energy as a result of an inelastic collision. Based on that probability, the average distance traveled before such a collision is known as the inelastic mean free path (IMFP) $\lambda_M(E)$. The IMFP is a function only of M and of E. Figure 2 shows a compilation of measurements of λ made by Seah and Dench [12], in terms of atomic monolayers as a function of kinetic energy. Note that both λ and energy scales are logarithmic. The important consequence of the dependence of λ on kinetic energy is that in the ranges of secondary electron kinetic energies used in XPS and AES, the values of λ are very small. In XPS, for example, typical ranges are 250 – 1500 eV, corresponding to a range of λ from about four to eight monolayers, while in AES, the energy range is typically 20 to 1000 eV, in which case λ would range from about two to six monolayers. What this means in practice is that if the photoelectron or the Auger electron is to escape into a vacuum and be detected, it must originate at or very near the surface of the solid. This is the reason why the electron spectroscopic techniques are surface specific.

2.1.2. Instrumentation

2.1.2.1. Vacuum Requirements

Electron spectroscopic techniques require vacua on the order of 10^{-8} Pa for their operation. This requirement arises from the extreme surface specificity of these techniques. With sampling depths of only a few atom layers, and elemental sensitivities down to 10^{-5} atom layers (i.e., one atom of a particular element in 10^5 other atoms in an atomic layer), the techniques are clearly very sensitive to surface contamination, most of which comes from the residual gases in the vacuum system. According to gas kinetic theory, for sufficient time to be available to make a surface-analytical measurement on a surface that has just been prepared or exposed, before contamination from the gas phase interferes, the base pressure

should be 10^{-8} Pa or lower, that is, in the region of ultrahigh vacuum (UHV).

Figure 2. Compilation by SEAH and DENCH [12] of measurements of inelastic mean free path as a function of electron kinetic energy
The solid line is a least-squares fit

The requirement for UHV conditions imposes restrictions on the types of material that can be used for the construction of surface analytical systems, or inside the systems, because UHV can be achieved only by accelerating the rate of removal of gas molecules from internal surfaces by raising the temperature of the entire system (i.e., by baking). Typical baking conditions are 150 – 200 °C for several hours. Inside the system, any material is permissible that does not produce volatile components either during normal operation or during baking. For example, brass, which contains the volatile metal zinc, can not be used. The principal construction material is stainless steel, with mu-metal (76 % Ni, 5 % Cu, 2 % Cr) used occasionally where magnetic screening is needed (e.g., around electron energy analyzers). For the same reasons, metal seals, not elastomers, are used for the demountable joints between individual components – the sealing material usually being pure copper although gold is sometimes used. Other materials that may be used between ambient atmosphere and UHV are borosilicate glass or quartz for windows, and alumina for electrical insulation for current or voltage connections.

Table 4. Energies and linewidths of some characteristic low-energy X-ray lines

Line	Energy, eV	Width, eV
$Y_{M\zeta}$	132.3	0.47
$Zr_{M\zeta}$	151.4	0.77
$Nb_{M\zeta}$	171.4	1.21
$Mg_{K\alpha}$	1253.6	0.70
$Al_{K\alpha}$	1486.6	0.85
$Si_{K\alpha}$	1739.5	1.00
$Y_{L\alpha}$	1922.6	1.50
$Zr_{L\alpha}$	2042.4	1.70

2.1.2.2. X-Ray Sources

The most important consideration in choosing an X-ray source for XPS is energy resolution. Equation (2.1) gives the relationship between the kinetic energy of the photoelectron, the energy of the X-ray photon, and the binding energy of the core electron. Since the energy spread, or linewidth, of an electron in a core level is very small, the linewidth of the photoelectron energy depends on the linewidth of the source if no undue broadening is introduced instrumentally. In XPS the analyst devotes much effort to extracting chemical information by means of detailed study of individual elemental photoelectron spectra. Such a study needs an energy resolution better than 1.0 eV if subtle chemical effects are to be identified. Thus the linewidth of the X-ray source should be significantly smaller than 1.0 eV if the resolution required is not to be limited by the source itself.

Other considerations are that the source material, which forms a target for high-energy electron bombardment leading to the production of X-rays, should be a good conductor to allow rapid removal of heat, and it should also be compatible with UHV.

Table 4 lists the energies and linewidths of the characteristic X-ray lines from a few possible candidate materials. In practice $Mg_{K\alpha}$ and $Al_{K\alpha}$ are the two used universally due to their line energies and width and their simple use as anode material.

For efficient production of X-rays by electron bombardment, exciting electron energies that are at least an order of magnitude higher than the line energies must be used, so that in Mg and Al sources accelerating potentials of 15 kV are employed. Modern sources are designed with dual anodes, one anode face being coated with

magnesium and the other with aluminum, and with two filaments, one for each face. Thus, a switch from one type of X irradiation to the other can be made very quickly.

To protect the sample from stray electrons from the anode, from heating effects, and from possible contamination by the source enclosure, a thin (ca. 2 µm) window of aluminum foil is interposed between the anode and the sample. For optimum X-ray photon flux on the surface (i.e., optimum sensitivity), the anode must be brought as close to the sample as possible, which means in practice a distance of ≈ 2 cm. The entire X-ray source is therefore retractable by means of a bellows and a screw mechanism.

The X radiation from magnesium and aluminum sources is quite complex. The principal $K\alpha$ lines are in fact unresolved doublets and should correctly be labeled $K\alpha_{1,2}$. Besides the $K\alpha_{1,2}$ lines, a series of further lines, so-called satellite lines, also exist, of which the more important ones are $K\alpha_{3,4}$. The energy separations of the satellite lines for Mg and Al and their intensities relative to $K\alpha_{1,2}$ are listed in Table 5.

Removal of satellites, elimination of the bremsstrahlung background, and separation of the $K\alpha_{1,2}$ doublet can be achieved by monochromatization, shown schematically in Figure 3. The X-ray source is positioned at one point on a spherical surface, called a Rowland sphere, and a quartz crystal is placed at another point. X-rays from the source are diffracted from the quartz, and by placing the sample at the correct point on the Rowland sphere, the $K\alpha_1$ component can be selectively focused on it. Quartz is a very convenient diffracting medium for $Al_{K\alpha}$ since the spacing between the $10\bar{1}0$ planes is exactly half the wavelength of the X radiation. Since the width of the $Al_{K\alpha_1}$ line is < 0.4 eV, the energy dispersion needed around the surface of the sphere implies that the Rowland sphere should have a diameter of at least 0.5 m. Although an XPS spectrum will be much "cleaner" when a monochromator is used, because satellites and background have been removed, the photon flux at the sample is much lower than that from an unmonochromatized source operating at the same power. Against this must be set the greatly improved signal-to-background level in a monochromatized spectrum.

2.1.2.3. Synchrotron Radiation

The discrete line sources described above for XPS are perfectly adequate for most applications, but some types of analysis require that the source be tunable (i.e., that the exciting energy be variable). The reason is to allow the photoionization cross section of the core levels of a particular element or group of elements to be varied, which is particularly useful when dealing with multielement semiconductors. Tunable radiation can be obtained from a synchrotron.

In a synchrotron, electrons are accelerated to near-relativistic velocities and constrained magnetically into circular paths. When a charged particle is accelerated, it emits radiation, and when the near-relativistic electrons are forced into curved paths, they emit photons over a continuous spectrum. The general shape of the spectrum is shown in Figure 4. For a synchrotron with an energy of several gigaelectronvolts and a radius of some tens of meters, the energy of the emitted photons near the maximum is on the order of 1 keV (i.e., ideal for XPS). As can be seen from the universal curve, plenty of usable intensity exists down into the UV region. With suitable monochromators on the output to select a particular wavelength, the photon en-

$K\beta$	48.0	2.0	70.0	2.0

ergy can be tuned continuously from about 20 to 500 eV. The available intensities are comparable to those from conventional line sources. The main advantage is the small beam diameter of the synchrotron radiation, which allows high spatial resolution.

λ_c = wavelength characteristic of the individual synchrotron

2.1.2.4. Electron Energy Analyzers

In electron spectroscopic techniques – among which XPS is the most important – analysis of the energies of electrons ejected from a surface is central. Nowadays the concentric hemispherical analyzer (CHA) is universally employed.

Energy analyzers cannot be discussed without a discussion of energy resolution, which is defined in two ways. *Absolute resolution* is defined as ΔE, the full width at half-maximum (FWHM) of a chosen peak. *Relative resolution* is defined as the ratio R of ΔE to the kinetic energy E of the peak energy position (usually its centroid), that is, $R = \Delta E/E$. Thus absolute resolution is independent of peak position, but relative resolution can be specified only by reference to a particular kinetic energy. In XPS, closely spaced peaks at any point in the energy range must be resolved, and this requires the same absolute resolution at all energies.

The CHA is shown in schematic cross section in Figure 5 [14]. Two hemispheres of radii r_1 (inner) and r_2 (outer) are positioned concentrically. Potentials $-V_1$ and $-V_2$ are applied to the inner and outer hemispheres, respectively, where V_2 is greater than V_1. The source S and the focus F are in the same plane as the center of curvature, and r_0 is the radius of the equipotential surface between the hemispheres. If electrons of energy $E = eV_0$ are injected at S along the equipotential surface, they will be focused at F if

$$V_2 - V_1 = V_0\,(r_2/r_1 - r_1/r_2) \tag{2.3}$$

Figure 5. Schematic of a concentric hemispherical analyzer [14]

If electrons are injected not exactly along the equipotential surface, but with an angular spread $\delta\alpha$ about the correct direction, then the energy resolution is given by

$$\Delta E/E = (w_S + w_F)\,/4r_0 + (\delta\alpha)^2 \tag{2.4}$$

where w_S and w_F are the respective widths of the entrance and exit slits. In most instruments, for convenience in construction, $w_S = w_F = w$, whereupon the resolution becomes

$$\Delta E/E = w/2r_0 + (\delta\alpha)^2 \quad (2.5)$$

In XPS the photoelectrons are retarded to a constant energy, called the pass energy, as they approach the entrance slit. If this were not done, Equation (5) shows that to achieve an absolute resolution of 1 eV at the maximum kinetic energy of about 1500 eV (with $Al_{K\alpha}$ radiation), and with a slit width of 2 mm, would require an analyzer with an average radius of about 300 cm, which is impracticable. Pass energies are selected in the range 20 – 100 eV for XPS, which allows the analyzer to be built with a radius of 10 – 15 cm.

Modern XPS spectrometers employ a lens system on the input to the CHA, which transfers an image of the analyzed area on the sample surface to the entrance slit of the analyzer. The detector system on the output of the CHA consists of several single channeltrons or a channel plate. Such a spectrometer is illustrated schematically in Figure 6.

Figure 6. Typical configuration in an XPS spectrometer

2.1.2.5. Spatial Resolution

A principal disadvantage of conventional XPS was the lack of spatial resolution; the spectral information came from an analyzed area of several square millimeters and was therefore an average of the compositional and chemical analyses from that area. However, many technological samples are inhomogeneous on a scale much smaller than that of conventional XPS analysis, and obtaining chemical information on the same scale as the inhomogeneities would be very desirable.

Improved XPS spatial resolution was achieved by using the focusing properties of the CHA described above, and this led to the development of the ESCASCOPE, now developed into the present ESCALAB 250 (VG Scientific, East Grinstead, UK), which acts as an XPS microscope. Here, a Fourier-transformed image is generated at the entrance slit of the CHA by introducing a third lens into the transferring lens system. The CHA disperses this image energetically, so that a Fourier-transformed image exists at the exit slit, but only for the energy selected by the setting of the CHA. This image is then inverted into a real image, which can be detected in the plane of a channel plate and a spatial resolution of about 3 µm is obtained.

A further development using the focusing properties of the transfer lens system is realized in the AXIS instruments (Kratos Analytical, Manchester, UK). Here, the principle plane of the first lens is moved towards the specimen by introducing a magnetic lens below the specimen holder. The spatial resolution is improved to about 15 µm without loss of intensity due to the simultaneous enhancement of the angle of acceptance.

A third development is realized in the Quantum 2000 (Physical Electronics, Eden Prairie, USA). Here, high-energy electrons of an electron gun are scanned over the surface of an Al anode, thereby generating an X-ray beam. This beam is then focused onto the specimen surface by an ellipsoidal monochromator and scans the specimen surface in the same rhythm as the electron beam is scanned. The X-ray beam is less than 10 µm in diameter, and the scanned area is 1.4×1.4 mm.

The thrust of development is toward ever-better spatial resolution, which means the smallest possible spot size on the sample compatible with adequate signal-to-noise ratio, for acquisition within a reasonable length of time.

2.1.3. Spectral Information and Chemical Shifts

Figure 7 shows a *wide-scan* or *survey XPS spectrum*, that is, one recorded over a wide range of energies, in this case 1000 eV. The radiation used was unmonochromatized $Al_{K\alpha}$, at 1486.6 eV, and the surface is that of almost clean copper. Such a spectrum reveals the major, or primary, features to be found, but to investigate minor or more detailed features, spectra are acquired over much more restricted energy ranges, at better energy resolution; the latter ones are called *narrow-scan spectra*.

Figure 7. Wide-scan spectrum from almost clean copper, recorded with $Al_{K\alpha}$ radiation

The primary features in Figure 7 are peaks arising from excitation of core level electrons according to Equation (2.1). At the low-energy end, two intense peaks are found at about 553 and 533 eV, corresponding to photoelectrons from the $2p_{3/2}$ and $2p_{1/2}$ levels of copper, respectively, the separation of 20 eV being the spin-orbit splitting. At the high kinetic energy end, there are three other copper photoelectron peaks at about 1363, 1409, and 1485 eV, which arise from the 3s, 3p, and 3d levels, respectively. The other primary features associated with copper are the three Auger peaks $L_3M_{4,5}M_{4,5}$, $L_3M_{2,3}M_{4,5}$, and $L_3M_{2,3}M_{2,3}$at 919, 838, and 768 eV, respectively. As pointed out in Section 2.1.1, the creation of a core hole by any means of excitation can lead to ejection of an Auger electron, so that in XPS, Auger features make a significant contribution to the spectrum. If Auger and photoelectron peaks happen to overlap in any spectrum, they can always be separated by changing the excitation (e.g., from $Al_{K\alpha}$ to $Mg_{K\alpha}$, or vice versa) since the Auger peaks are invariant in energy (Eq. 2.2) whereas the photoelectron peaks must shift with the energy of the exciting photons according to Equation (2.1).

In addition to primary features due to copper in Figure 7, there are small photoelectron peaks at kinetic energies of 955 and 1204 eV that arise from the oxygen and carbon 1s levels, respectively, due to the presence of some contamination on the surface. Secondary features are X-ray satellite and ghost lines, surface and bulk plasmon energy loss features, shake-up lines, multiplet splitting, shake-off lines and asymmetries due to asymmetric core levels [15].

Chemical shift is the observed shift in energy of a photoelectron peak from a particular element when the chemical state of that element changes. When an atom enters into combination with another atom or group of atoms, an alteration occurs in the valence electron density, which can be positive or negative according to whether charge is accepted or donated, and this causes a consequent alteration in the electrostatic potential affecting the core electrons. Therefore the binding energies of the core electrons change, giving rise, according to Equation (2.1), to shifts in the corresponding photoelectron peaks. Tabulation of the chemical shifts experienced by any one element in a series of pure compounds of that element thus enables its chemical state to be identified during analysis of unknown samples. Many such tabulations have appeared, and a major collection of them can be found in [2]. The identification of chemical state in this way is the principal advantage of XPS over other surface analytical techniques.

An example of a spectrum exhibiting a chemical shift is that of the tin 3d peaks in Figure 8. A thin layer of oxide on the metallic tin surface allows photoelectrons from both the underlying metal and the oxide to appear together. Resolution of the doublet $3d_{5/2}$, $3d_{3/2}$ into the components from the metal (Sn^0) and from the oxide Sn^{n+} is shown in Figure 8 B. The shift in this case is 1.6 – 1.7 eV. Curve resolution is an operation that can be performed routinely in data-processing systems associated with photoelectron spectrometers.

2.1.4. Quantification, Depth Profiling, and Imaging

2.1.4.1. Quantification

If an X-ray photon of energy $h\nu$ ionizes a core level X in an atom of element A in a solid, the photoelectron current I_A from X in A is

$$I_A(X) = K\,\sigma_A(h\nu,X)\,\beta_A(h\nu,X)\,\bar{N}_A\,\lambda_M(E_A)\cos\theta \qquad (2.6)$$

where $\sigma_A(h\nu, X)$ is the photoelectric cross section for ionization of X (binding energy E_B) by photons of energy $h\nu$; $\beta_A(h\nu, X)$ the asymmetry parameter for emission from X by excitation with photons of energy $h\nu$; $\bar{N}_A$ the atomic density of A averaged over depth of analysis; $\lambda_M(E_A)$ the inelastic mean free path in matrix M containing A, at kinetic energy E_A, where $E_A = h\nu - E_B$; and θ the angle of emission to surface normal. K is a constant of proportionality that contains fixed operational parameters such as incident X-ray flux, transmission of the analyzer at kinetic energy E_A, and efficiency of the detector at kinetic energy E_A, kept fixed during any one analysis.

Values of the total cross section σ_A for $Al_{K\alpha}$ radiation, relative to the carbon 1s level, have been calculated by Scofield [16], and of the asymmetry parameter β_A by Reilman et al. [17]. Seah and Dench [12] (Fig. 2) have compiled many measurements of the inelastic mean free path, and for elements the best-fit relationship that they found was

$$\lambda_M(E) = 538E^{-2} + 0.41\,(aE)^{1/2}\ \text{monolayers} \qquad (2.7)$$

where a is the monolayer thickness in nanometers.

In principle, therefore, the surface concentration of an element can be calculated from the intensity of a particular photoelectron emission, according to Equation (2.6). In practice, the *method of relative sensitivity factors* is in common use. If spectra were recorded from reference samples of pure elements A and B on the same spectrometer and the corresponding line intensities are I_A^∞ and I_B^∞, respectively, Equation (2.6) can be written as

$$\frac{I_A/I_A^\infty}{I_B/I_B^\infty} = \left(\frac{\lambda_M(E_A)\,\lambda_B(E_B)}{\lambda_M(E_B)\,\lambda_A(E_A)}\right)\left(\frac{R_B^\infty}{R_A^\infty}\right)\left(\frac{N_A N_B^\infty}{N_B N_A^\infty}\right) \qquad (2.8)$$

where R_A^∞ and R_B^∞ are factors for the reference samples, depending on the roughness of the surfaces, and N_A^∞ and N_B^∞ are the atomic densities of the reference samples. From the above equation the ratio N_A/N_B can be obtained from the measured intensity ratio I_A/I_B. However the accuracy of quantitative results is only as good as the accuracy of the ingoing parameter and the intensity values I_A and I_B. These intensities are simply the areas under the line peaks after background subtraction. Three different procedures are commonly in use: straight line subtraction, Shirley's method, and Tougaard's method. With the last-mentioned method, the measured spectrum is deconvoluted into the primary (true) excited spectrum by taking into account that the emitted electrons suffer an energy loss due to scattering during travelling in the solid.

A further critical point are the intensities I^{∞} correlated to spectra of the pure elements. Calculated and experimentally determined values can diverge considerably, and the best data sets for I^{∞} measured on pure reference samples still show a scatter of up to 10 %. The use of an internal standard or a simultaneously measured external standard seems to be the most successful way to decrease the inaccuracy to below 10 %. (For a more detailed discussion of background subtraction and quantification, see [18].)

2.1.4.2. Depth Profiling

Very often, in addition to analytical information about the original surface, information is required about the distribution of chemical composition to depths considerably greater than the inelastic mean free path. Nondestructive methods such as variation of emission angle or variation of exciting photon energy are possible, but they are limited in practice to evaluation of chemical profile within depths of only ca. 5 nm. Obtaining information from greater depths requires destructive methods, of which the one used universally is removal of the surface by ion bombardment, also called sputtering. The combination of removal of the surface by sputtering and of analysis by XPS, AES, or SSIMS is termed depth profiling. Instrumentally, this is performed by means of ion guns which are described elsewhere (see Section 3.1.1.1.1). Depth profiling in XPS is mostly performed with a noble gas to minimize chemical effects. In compounds, preferential sputtering, e.g., of O from TiO_2 surfaces and of Be from Cu – Be alloys, may occur. This is easily comprehensible in terms of the different surface binding energies and different momenta transferred to atoms with different masses. Preferential sputtering frequently results in a chemically modified surface, even if the primary ion from the ion gun is not chemically reactive after its (immediate) neutralization in the solid.

The depth resolution achievable during profiling depends on many variables, and the reader is referred to the comprehensive discussion in [18].

In XPS, chemical information is comparatively slowly acquired in a stepwise fashion along with the depth, by using alternate cycles of sputtering and analysis. Examples of profiles through oxide films on pure iron and on Fe – 12Cr – 1Mo alloy are shown in Figure 9, in which the respective contributions from the metallic and oxide components of the iron and chromium spectra have been quantified [19]. In these examples the oxide films were only ≈5 nm thick on iron and ≈3 nm thick on the alloy.

Figure 9. Depth profiles of thin (3 – 5 nm) oxide films [19] on
A) Pure iron; B) Fe – 12 Cr – 1 Mo alloy

Current practice in depth profiling is to use positively charged argon ions at energies between 0.5 and 10 keV, focused into a beam of 2 – 5 µm diameter, which is then rastered over the area to be profiled. The area bombarded by the primary ion beam, which is typically finely focused and rastered, should be significantly greater than the analyzed area, so that only the flat bottom of the sputtered crater is analyzed. Ion current densities are variable between 5 and

50 μA/cm^2. Uniformity of sputtering, and therefore the depth resolution of the profile, can be improved by rotating the sample during bombardment.

During the sputtering process, many artifacts are introduced that can affect quantification; some of these derive from the nature of the sample itself (e.g., roughness, crystalline structure, phase distribution, electrical conductivity), and others are radiation-induced (e.g., atomic mixing, preferential sputtering, compound reduction, diffusion and segregation, sputter-induced topography). This is an extensive subject in its own right; a discussion of all aspects is given in [20].

State of the art for data evaluation of complex depth profile is the use of factor analysis. The acquired data can be compiled in a two-dimensional data matrix in a manner that the n intensity values $N(E)$ or, in the derivative mode $\mathrm{d}N(E)/\mathrm{d}E$, respectively, of a spectrum recorded in the ith of a total of m sputter cycles are written in the ith column of the data matrix $\boldsymbol{D}$. For the purpose of factor analysis, it now becomes necessary that the $(n \times m)$-dimensional data matrix $\boldsymbol{D}$ can be expressed as a product of two matrices, that is, the $(n \times k)$-dimensional *spectrum matrix* $\boldsymbol{R}$ and the $(k \times m)$-dimensional *concentration matrix* $\boldsymbol{C}$, in which $\boldsymbol{R}$ contains the spectra of k components in k columns, and $\boldsymbol{C}$ contains the concentrations of the respective m sputter cycles in k rows, i.e.

$$\boldsymbol{D} = \boldsymbol{R} \cdot \boldsymbol{C} + \boldsymbol{E} \tag{2.9}$$

$\boldsymbol{E}$ is an error matrix taking errors of measurement (e.g., random noise) into consideration. The term *component* describes such chemical or physical states whose spectra cannot be generated by a linear combination of the other components. Thus, components can be elements, chemical compounds – stoichiometric or nonstoichiometric – or even states induced by physical processes, provided that the spectra differ significantly, for example, in line shapes or line shifts.

Since the introduction of factor analysis for evaluation of depth profile data by Gaarenstroom [21], many papers have been published [22–29]. With the help of factor analysis, three results can directly be achieved: (1) the number k of relevant components which are necessary to create the data matrix, (2) the so-called abstract spectrum matrix $\boldsymbol{R}*$ and the abstract concentration matrix $\boldsymbol{C}*$, and (3) a new data matrix $\boldsymbol{D}*$, which can be generated from $\boldsymbol{R}*$ and $\boldsymbol{C}*$ by leaving out the so-called noise components.

If the spectra of the k relevant components are known, the abstract matrices can be transformed into interpretable spectrum and concentration matrices, respectively, and as a final result, one obtains the required *component depth profile*. If one or more of the spectra of the k relevant components is not known, a quantified component depth profile cannot be constructed.

New developments which have still to be checked for their usability in data evaluation of depth profiles are *artificial neural networks* [25], [30–34], *fuzzy clustering* [35], [36], and *genetic algorithms* [37].

2.1.4.3. Imaging

As already mentioned in Section 2.1.2.5 the ESCALAB acts as an XPS microscope and the result is called an *elemental map* or *image*. An example of *chemical state imaging* is given in Figure 10 [38]. The material is a contaminated fluoropolymer, the contamination being in the form of dark spots of 10 – 80 μm in size. Both images in Figure 10 are in the C 1s photoelectron peak, but of different chemical states, that is, different binding energies. The upper is in that contribution arising from carbon bound to fluorine, and the lower from carbon bound to carbon (i.e., graphitic in nature). The complementarity of the images indicates that the contamination is graphitic in nature.

If the analyzer is set to accept electrons of an energy characteristic of a particular element, and the incident X-ray beam is rastered over the surface to be analyzed, then a visual display whose intensity is modulated by the peak intensity will correspond to the distribution of that element over the surface. The result is also an *image*, and this technique is realized with the Quantum 2000.

When the whole sample surface is irradiated by the exciting X-rays, an image can be obtained in a different way: The spot accepted by the transferring lens system in front of the input of the CHA is rastered by introducing deflector plates in front of the lens system. Again,

only electrons of a characteristic energy can pass the analyzer. This technique is realized with the AXIS series.

Figure 10. Chemical state images obtained with an ESCASCOPE, from a contaminated fluoropolymer [198]
A) Image in contribution to C 1s from C–F bonding; B) Image in contribution to C 1s from C–C bonding

Tonner et al. have recorded scanning XPS microscographs at the Advanced Light Source synchrotron radiation center of Lawrence Berkeley National Laboratory [15]. They investigated a polished and sputter-cleaned surface of mineral ilmenite with the nominal composition of $FeTiO_3$, and used the Fe 3p and Ti 3p lines for imaging. Using synchrotron radiation they demonstrated a spatial resolution of about 0.25 µm.

Care must be taken in interpreting the intensity distribution, since the electron intensity depends not only on the local concentration of the element but also on the topography, because surface roughness can affect the inelastic background underneath the line. Therefore, elemental maps are customarily presented as variations of the ratio of peak intensity divided by the magnitude of the background on one or both sides of the line, which can be carried out easily by computer.

2.1.5. The Auger Parameter

Section 2.1.3 shows that in an XPS spectrum, X-ray excited Auger peaks are often as prominent as the photoelectron peaks themselves. For many elements, the chemical shifts in Auger peaks are actually greater than the shifts in photoelectron peaks. The two shifts can be combined in a very useful quantity called the Auger Parameter $\alpha*$, first used by Wagner [39] and defined in its modified form [40] as

$$\alpha* = E_{\mathrm{kin}}\,(XYZ) + E_{\mathrm{B}}\,(W) \tag{2.10}$$

where $E_{\mathrm{kin}}\,(XYZ)$ is the kinetic energy of the Auger transition XYZ, and $E_{\mathrm{B}}\,(W)$ is the binding energy of an electron in level i. The Auger and photoelectron peak energies must be measured in the same spectrum.

The parameter $\alpha*$ is independent of photon energy and has the great advantage of being independent of any surface charging. It is therefore measurable for all types of material from metals to insulators. Extensive tabulations of $\alpha*$ have appeared, based on a large number of standard materials, and the most reliable have been collected by Wagner [41].

As defined in Equation (2.10), $\alpha*$ is purely empirical; any prominent and conveniently situated Auger and photoelectron peaks can be used. If $\alpha*$ is defined slightly more rigorously, by replacing $E_{\mathrm{B}}\,(W)$ by $E_{\mathrm{B}}\,(X)$ in Equation (2.10), it is related closely to a quantity called the extra-atomic relaxation energy R^{ea}, since $\Delta\alpha*$ can be shown to equal $2\,\Delta R^{\mathrm{ea}}\,(X)$. In other words, the change in Auger Parameter between two chemical states is equal to twice the change in the extraatomic relaxation energies in the two states, associated with the hole in the core level X. Thus $\alpha*$ has an important physical basis as well as being useful analytically.

2.1.6. Applications

XPS has been applied in virtually every area in which the properties of surfaces are important. The most prominent areas can be drawn

from conferences on surface analysis, especially from the ECASIA, which is held every two years. These areas are: adhesion, biomaterials, catalysis, ceramics and glasses, corrosion, environmental problems, magnetic materials, metals, micro- and optoelectronics, nanomaterials, polymers and composite materials, superconductors, thin films and coatings, and tribology and wear. Furthermore, the proceedings of these conferences give a representative survey on current surface-analytical problems and studies [42], [43]. Given below are a few selected examples from the areas mentioned above; for more comprehensive discussions of the applications of XPS, see [1], [3–9], [44–49].

2.1.6.1. Catalysis

An understanding of the basic mechanisms of catalysis has been one of the major aims of XPS from its inception. To this end the technique has been used in two ways: (1) in the study of "real" catalysts closely resembling those used industrially; (2) in the study of "model" catalysts, where the number of parameters has been reduced by the use of well-characterized crystal surfaces.

For industrial catalysts the chemical information obtainable from XPS is all important, since the course and efficiency of the catalyzed reaction will be governed by the states of oxidation of the elements at the surface. Hence, XPS is used to analyze both elemental and chemical composition as a function of bulk composition, of surface loading where the active material is deposited on a support, of oxidation and reduction treatments, and of time in reactor under operating conditions. Figure 11 demonstrates the effect on the chemical state of molybdenum in the surface of Mo – Sm – O catalysts of various compositions [50]. For the highest concentration of molybdenum (spectrum d) the Mo 3d doublet is very similar to that of MoO_3, but at the samarium-rich composition (spectrum a), it is more like that of a molybdate or a mixed oxide. The effect of successive reduction treatments on a cobalt – molybdenum – alumina catalyst is shown in the changes in the Mo 3d spectra of Figure 12 [51]. The air-fired catalyst in spectrum a contains entirely Mo^{VI} at the surface, but with repeated hydrogen reduction the spectrum changes radically and can be curve-resolved into Mo^{VI}, Mo^{V}, and Mo^{IV} contributions. The chemical state of the surface in spectrum f contains approximately equal proportions of these three oxidation states.

Mo : Sm ratios are a) 0.25; b) 1.33; c) 4.00; d) 8.00

PIJPERS et al. [52] reviewed the application of XPS in the field of catalysis and polymers. Other applications of XPS to catalytic problems deal with the selective catalytic reduction of NO_x on Pt- and Co-loaded zeolites. Although the Al 2p line (Al from zeolite) and Pt 4f line interfere strongly, the two oxidation states Pt^0 and Pt^{II} can be distinguished after careful curve fitting [53]. The influence of Zn deposition on Cu(111) surfaces in methanol synthesis by hydrogenation of CO_2 shows that Zn creates sites that stabilize the formate intermediate and thus promote the hydrogenation process [54]. Further publications deal with methane oxidation by various layered rock-salt-type oxides [55]; poisoning of vanadia in VO_x/TiO_2 by K_2O leading to a lower reduction capability of vanadia due to the formation of V^V [56], and interaction of SO_2 with Cu, Cu_2O,

and CuO showing temperature-dependent SO_2 absorption or sulfide formation [57].

2.1.6.2. Polymers

Polymers have been the most prominent objects of investigation since XPS became commercially available in the late 1960s. Nowadays XPS is still one of the most widely applied methods for characterizing polymer surfaces. "Bibles" of high resolution XP spectra of more than a hundred different organic polymers have been published by Beamson and Briggs [58] and Briggs [59]. A crucial problem is the X-ray degradation that takes place in a more or less pronounced manner on virtually all polymer surfaces. Therefore, one has to exercise caution in investigating polymer surface reactions and respective quantification; in practice this means reducing the radiation time of the exciting X-rays.

Since polymers are typically nonconductive, sample charging can occur and has to be compensated carefully, for example, by a low-energy electron flood gun, to avoid lineshape distortion and misinterpretation of the measurements.

The photoelectron line of main interest is C 1s. Different bonding environments of the carbon atom lead to very small chemical shifts of this line. Therefore, high-resolution XPS is required, and monochromatic radiation should be applied to avoid overlaps with satellite lines.

Many publications appear every year dealing with the analysis of polymers, and a few examples are given here. Butyl rubbers are mainly used in tire production, and to study the influence of different polymers on the surface chemistry and to determine the adhesion of bromobutyl blends as a function of temperature, valence-band XPS was applied to a variety of pure polymers and different butyl – elastomer blends. These investigations show the value of valence-band XPS for polymers, which are not easy to analyze by core-level XPS [60]. In a study dealing with the enhancement of the adhesion strength of the interface Cu – polyimide, polyimide surfaces were subjected to a plasma treatment, and the modified surfaces were studied by TOF-SIMS/XPS [61]. More than 80 review articles appeared since 1995 dealing with special problems in polymer analysis, for example, polymer membranes [62], polymeric biomedical and optoelectronic applications [63], and the current status of XPS instrumentation in polymer analysis [64].

2.1.6.3. Corrosion and Passivation

Besides the application of XPS in catalysis, the study of corrosion mechanisms and corrosion products is another main area of application. Special attention has to be devoted to artefacts as a consequence of X-ray irradiation. For example, reduction of metal oxides (e.g., $CuO \rightarrow Cu_2O$) can take place, loosely bound

water or hydrates may be desorbed in the spectrometer vacuum, and decomposition of hydroxides may occur. Thorough investigations are supported by other surface-analytical and/or microscopic techniques like AFM, which is gaining increasing importance.

Corrosion products that are formed as thin layers on metal surfaces in aqueous or gaseous environments, along with the nature and stability of passive and protective films on metals and alloys, have also been major areas of XPS application. XPS has been used in two ways, one in which materials corroded or passivated in the natural environment are analyzed, and another in which well-characterized, usually pure metal surfaces are studied after exposure to controlled conditions.

More effort has probably been devoted to study of the corrosion and passivation properties of Fe – Cr – Ni alloys such as stainless steel and other transition-metal alloys than to any other metallic system [52], [54, 65, 66]. The type of spectral information obtainable from an Fe – Cr alloy of technical origin, carrying an oxide and contaminant film after corrosion, is shown schematically in Figure 13 [67].

Corrosion-inhibiting organic films on steel were studied by XPS [68], and investigations on inhibiting films formed in sea water [69] showed their stability, that is, no pitting corrosion was observed. Protective layers, frequently TiN, deposited on different materials are of major interest. Investigations on TiN coatings exposed to different humid SO_2-containing aggressive environments show that the most aggressive atmosphere can penetrate through pores towards the interface TiN – Fe and cause corrosion [70]. The corrosion behavior of sandwich-structured TiN – Ti layers was also investigated [71].

Biocorrosion of stainless steel occurs due to exopolymer-producing bacteria. It was shown that Fe is accumulated in the biofilm [72]. The influence of bacteria on the corrosion behavior of Mo metal surface was also investigated by XPS [73]. These last two mentioned investigations indicate a new field of research in which XPS can be employed successfully. XPS has also been applied to studying the corrosion of glasses [74], of polymer coatings on steel [75], of tooth-filling materials [76], and to investigate the role of surface hydroxyl groups of oxide films on metals [77] or other passive films.

2.1.6.4. Adhesion

The adhesion of metal and ink to polymer, as well as the adhesion of paint and coating to metal, are of vital importance in several technologies. In the aircraft industry, aluminum-to-aluminum adhesion is employed. The strength and durability of an adhesive bond depend absolutely on the way in which the adhesive compound interacts with the surfaces to which it is supposed to adhere, which in turn often involves pretreatment of the surfaces to render them more reactive. The nature and degree of the reactivity are functions of the chemical states of the adhering surfaces; these states can be monitored by XPS.

In electronic packaging technology, metal – polymer adhesion has been important for some years. Many studies have been devoted to the interactions between metals and polymers, and that of Chin-An Chang et al. [78] is a good example. They deposited 200-nm-thick films of copper, chromium, titanium, gold, and aluminum on various fluorocarbon polymer films, and found that adhesion in terms of peel strength was highest for titanium. Figure 14 shows the C 1 s spectra after metal deposition; they reveal that for titanium, and to a lesser extent chromium, a strong carbide bond is formed, as evidenced by the peak at 282 – 283 eV. With the other metals, very low adhesion was found, and no carbide-like peaks occurred.

The path of failure of an adhesive joint can give information about the mechanism of failure if analysis of the elemental and chemical composition can be carried out along the path. Several authors have performed such analyses by loading the adhesive joint until it fractures and then using XPS to analyze each side of the fracture.

The complementary use of XPS and TOF-SIMS was demonstraded by Fitzpatrick et al. and Watts et al. [79], [80] who studied the failure of hot-dipped galvanized steel pretreated with a zinc phosphate conversion coating and joined with epoxy. They found that the observed electrochemical activity is due to degradation at the zinc – polymer interface and is responsible for the ingress of aggressive substances. Furthermore Wolany et al. [81] investigated the adhesion of untreated and plasma-modified poly-

Figure 13. Schematic of type of information obtainable from XPS spectra from an Fe – Cr alloy with an oxide film underneath a contaminant film [67]

imide by XPS and static SIMS. They showed that the number and kind of functional groups available for adhering bonds were enhanced by plasma treatment and that the adhesion strength for Cu deposition was improved. This was also corroborated by SIMS.

Recently, XPS was used to study the effects of thermal treatment on the morphology and adhesion of the interface between Au and the polymer trimethylcyclohexane-polycarbonate [82]; the composition of the surfaces and interfaces of plasma-modified Cu – PTFE and Au – PTFE, as well as the surface structure and the improvement of adhesion [83]; the influence of excimer laser irradiation of the polymer on the adhesion of metallic overlayers [84]; and the behavior of the Co-rich binder phase of WC – Co hard metal and the deposition of diamond thereon [85].

2.1.6.5. Superconductors

In the years since the discovery of superconducting oxides in 1986, many papers have been published describing the application of XPS to superconductors. One reason for this frenzied activity has been the search for the precise mechanism of superconductivity in these materials.

Figure 14. The C 1s XPS spectra recorded by Chin-An Chang et al. [78] from perfluoroalkoxy polymer (PFA)
a) Before deposition; b) Deposition of copper; c) Deposition of chromium; d) Deposition of titanium

An essential piece of information concerns the chemical states of the constituent elements, particularly copper, which is common to all of them. Some theories predict that small but

significant amounts of the Cu^{3+} state should occur in superconductors, but other models disagree. Comparison by STEINER et al. [86] of the Cu $2p_{3/2}$ spectra from copper compounds containing copper as Cu^0 (metal), Cu^+, Cu^{2+}, and Cu^{3+}, with the spectra from the superconducting oxide $YBa_2Cu_3O_7$ and from the base material La_2CuO_4, showed conclusively that the Cu^{3+} contribution to the superconducting mechanism must be negligible. Some of their comparative spectra are shown in Figure 15. The positions of the Cu $2p_{3/2}$ peak in $YBa_2Cu_3O_7$ and La_2CuO_4, along with the satellite structure, are very similar to that in CuO (i.e., Cu^{2+}, rather than in $NaCuO_2$, which contains Cu^{3+}).

Figure 15. Comparison of the Cu $2p_{3/2}$ and satellite XPS spectra from several copper compounds with the spectrum from the superconducting oxide $YBa_2Cu_3O_7$ [86]
a) CuO, $\Gamma = 3.25$ eV; b) La_2CuO_4, $\Gamma = 3.30$ eV; c) $YBa_2Cu_3O_7$, $\Gamma = 3.20$ eV; d) $NaCuO_2$, $\Gamma = 1.60$ eV; e) Cu^{2+} satellites

Much effort in superconductor research has been devoted to fabricating thin films with the same superconducting properties as the bulk material, and to prepare suitable electrical contact to the surfaces of superconductors. XPS has been of great use in both areas through its ability to monitor both composition and chemical state during the processes either of thin superconducting film formation, or of the deposition of thin conducting and semiconducting films onto a superconducting surface. Typical of the latter studies is that of ZIEGLER et al. [87], who deposited increasing amounts of silicon onto epitaxial films of $YBa_2Cu_3O_{7-x}$. Figure 16 shows the Si 2p and Ba 4d spectra during the deposition of silicon and after heating the films in oxygen at 250 °C once 6 nm of silicon had accumulated [86]. The Ba 4d spectrum at the bottom can be resolved into three $4d_{5/2,3/2}$ doublets, corresponding – with increasing energy – to barium in the bulk superconductor, in the surface of the superconductor, and as carbonate. With increasing silicon thickness the barium spectrum attenuates but does not change in character, but silicon does not appear in the spectrum until nearly 5 nm has been deposited, suggesting migration into the superconductor at room temperature. At a thickness of 6 nm, the Si 2p spectrum can be separated into suboxide contributions, indicating reaction of silicon with the $YBa_2Cu_3O_{7-x}$ surface. After heating in oxygen the Si 2p spectrum changes to that characteristic of SiO_2 and silicates, while the Ba 4d spectrum also changes by increasing in intensity and conforming mostly to that expected of a barium silicate. As a result of the latter changes the superconducting properties of the film were destroyed. The Y 3d and Cu 2p spectra establish that yttrium and copper oxides are formed as well.

Other surface reactions studied have been those of gold [88] and silver [89] with $Bi_2Sr_2CaCu_2O_{8+y}$, of niobium with $YBa_2Cu_3O_{7-x}$ [90], and of lead with $YBa_2Cu_3O_{7-x}$ [91], [92]. Characteristics of superconductors in the form of thin films prepared in several ways have been recorded by XPS for $YBa_2Cu_3O_{7-x}$ [93–97], $GdBa_2Cu_3O_{7-x}$ [98], $Nd_{2-x}Ce_xCuO_{4-y}$ [99], $Rb_xBa_{1-x}BiO_3$ [100], $(Bi_{0.9}Pb_{0.1})_{2.3}Sr_2Ca_{1.9}Cu_3O_{10+x}$ [101], and $Tl_2Ca_2Ba_2Cu_3O_{10}$ [102]. Detailed electronic studies have been made on the bulk superconductors $Bi_2Sr_2Ca_{1-x}Nd_xCu_2O_y$ [103], [104], $Nd_{2-x}Ce_xCuO_{4-y}$ [105–109], $ErBa_2Cu_4O_8$ [110], and $Tl_2Ba_2CaCu_2O_8$ [111].

In a number of applications depth profiles were recorded with the aim of investigating the extent of reaction of various materials with superconductors, or analyzing the uniformity and concentration during preparation of superconductors. Such investigations were carried out with XPS as well as AES.

2.1.6.6. Interfaces

The chemical and electronic properties of elements at the interfaces between very thin films

and bulk substrates are important in several technological areas, particularly microelectronics, sensors, catalysis, metal protection, and solar cells. To study conditions at an interface, depth profiling by ion bombardment is inadvisable since both composition and chemical state can be altered by interaction with energetic positive ions. The normal procedure is therefore to start with a clean or other well-characterized substrate and deposit the thin film onto it slowly at a chosen temperature while XPS monitors the composition and chemical state by recording selected characteristic spectra. The procedure continues until no further spectral changes occur, as a function either of film thickness, of time elapsed since deposition, or of changes in substrate temperature. A good example is the study of the reaction at the interface of the rare-earth element thulium with the silicon (111) surface [112]. Figure 17 shows the Si 2p spectrum from the substrate as thulium is deposited on it at room temperature. With the $Mg_{K\alpha}$ radiation used for the analysis, the kinetic energy of the Si 2p electrons is about 1155 eV, corresponding to an inelastic mean free path of about 2 nm. The Si 2p peak eV is still plainly detectable after 12.5 nm of thulium has been deposited, and in addition a new feature appears on the low binding energy side of the peak, increasing in magnitude and shifting to lower energy with thickness. Raising the temperature in stages for the thickest film and use of X-ray diffraction established that the energetic final position labeled R_1 corresponded to Tm_5Si_3, and the initial energetic position found at a thickness of 0.5 – 1.0 nm, to $TmSi_2$. However, the magnitude of the residual Si 2p peak was too great at all stages to be accounted for by compound formation alone, indicating the formation of thulium clusters followed by their coalescence into islands. Measurement of the Tm $4d_{5/2}$ binding energy during the interaction also showed that the oxidation state of thulium was +3 at all temperatures and coverages.

Studies of interfaces by XPS have been carried out on U – Si(111)-7×7 surface [113], on interfaces forming during the oxidation of $Ti_{1-x}Al_xN$ ($x = 0.2 - 0.65$) [114], on $ZrO_2 - Y_2O_3$ on steel [115], on naphthalocyanine on Si(111)-7×7 and Si(100)-2×1 faces [116], and on a phenylacetylene – *p*-nitrophenylacetylene copolymer on Cr [117]. These five examples show that in the different areas of application discussed so far, interfaces play a dominant role, because they determine the chemical and electronic properties of the effectiveness of adhesives, the adhesion of protective or decorative coatings, the functionality of microelectronics and sensors, and the behavior of catalysts.

Other important areas of application of XPS have included lubricating films [118], [119], glasses [120–124], ion implantation [125–129], and cleaning [130–132] and passivation [133], [134] of semiconductor surfaces.

2.2. Ultraviolet Photoelectron Spectroscopy (UPS)

In its principle of operation, UPS is similar to XPS, in that a surface is irradiated with photons and the energies of the ejected photoelectrons are analyzed. The physical relationship involved is the same as that of Equation (2.1) for

XPS, but in UPS the energy $h\nu$ of the exciting photons is much lower since the photons are derived from a gaseous discharge that produces hard UV radiation. The gas normally used is helium, which, depending on pressure conditions in the discharge, will provide line sources of energy 21.21 eV (He I) or 40.82 eV (He II) with very narrow linewidths (≈20 meV). Because of these low exciting energies, the binding energies E_B that appear in Equation (2.1) refer not to core levels, as in XPS, but to shallow valence band levels and to other shallow levels, such as those of adsorbates, near the valence band. For energy analysis, the CHA is again used, but the pass energies employed for UPS are much lower than in XPS since better energy resolution is required.

UPS is not an analytical technique in the sense that it can provide quantified elemental concentrations on a surface as XPS and AES can, but it is a powerful tool in basic research and is another of the group of most frequently used techniques. It is used in two ways. In its *angle-integrated* form it has been employed very extensively in studying the interactions of gaseous molecules with surfaces, usually in combination with other techniques such as XPS, AES, LEED, and TDS. The other way in which it has been used is in *angle-resolved UPS* (ARUPS). In this form the energy analyzer, a CHA of small radius, is mounted in such a way mechanically that it can traverse the space around the sample in both polar and azimuthal directions, while the angle of photon incidence is kept constant. The angle of incidence is then changed by rotation of the sample. If the sample is a single crystal with a clean surface, the dispersion of spectral features (i.e., their movement along the energy axis and their increase or decrease in magnitude) can be used theoretically to plot the band structure in the surface region. The changes in surface-associated band structure during reaction with gaseous molecules can then be followed, leading to additional information about the nature of the reaction.

2.3. Auger Electron Spectroscopy (AES)

After XPS, AES is the next most widely used surface analytical technique. As an accepted surface technique, AES actually predates XPS by two to three years, since the potential of XPS as a surface-specific technique was not recognized immediately by the surface science community. Pioneering work was carried out by Harris [135] and by Weber and Peria [136], but the technique as it is known today is basically the same as that established by Palmberg et al. [137].

a) Clean silicon; b) 0.2 nm Tm; c) 0.5 nm Tm; d) 2 nm Tm; e) 4 nm Tm; f) 6.5 nm Tm; g) 12.5 nm Tm

2.3.1. Principles

The surface to be analyzed is irradiated with a beam of electrons of sufficient energy, typically in the range of 2 – 10 keV, to ionize one or more core levels in surface atoms. After ionization the atom can then relax by either of the two processes described in Section 2.1 for XPS, that is, ejection of a characteristic X-ray photon (fluorescence) or ejection of an Auger electron. Al-

though these are competing processes, for shallow core levels ($E_B < 2$ keV) the probability of the Auger process is far higher. The Auger process is described schematically in Figure 1 (left), which points out that the final state of the atom is doubly ionized.

Equation (2.2) shows that the Auger energy is a function only of atomic energy levels. Since no two elements have the same set of atomic binding energies, analysis of Auger energies provides elemental identification. Even if levels L_1 and L_{23} are in the valence band of the solid, analysis is still possible because the dominant term in Equation (2.2) is always the binding energy of K, the initially ionized level.

Since heavy elements have more levels than just K and L, Equation (2.2) also indicates that the heavier the element, the more numerous are the possible Auger transitions. Fortunately, large differences exist in the probabilities between different Auger transitions, so that even for the heaviest elements, only a few intense transitions occur, and analysis is still possible.

In principle, chemical as well as elemental information should be available in AES, since the binding energies appearing in Equation (2.2) are subject to the same chemical shifts as measured in XPS. In practice, since the binding energies of three levels are involved, extracting chemical information from Auger spectra is, in most cases, difficult. However, significant progress has been made in data-processing methods (see Section 2.1.4.2) yielding valuable chemical information.

The reasons why AES is one of the surface-specific techniques are given in Section 2.1.1, with reference to Figure 2. The normal range of kinetic energies recorded in an AES spectrum would typically be from 20 to 1000 eV, corresponding to inelastic mean free path values of 2 – 6 monolayers.

The nomenclature used in AES is also mentioned in Section 2.1.1. The Auger transition in which initial ionization occurs in level X, followed by the filling of X by an electron from Y and ejection of an electron from Z, would therefore be labeled XYZ. In this rather restricted scheme, one would thus find in the KLL series the six possible transitions KL_1L_1, KL_1L_2, KL_1L_3, KL_2L_2, KL_2L_3, and KL_3L_3. Other combinations could be written for other series such as the LMM, MNN, etc.

2.3.2. Instrumentation

2.3.2.1. Vacuum Requirements

The same considerations discussed in Section 2.1.2.1 for XPS apply to AES.

2.3.2.2. Electron Sources

The energy of the exciting electrons does not enter into Equation (2.2) for the Auger energy, unlike that of the exciting X-ray photon in XPS; hence the energy spread in the electron beam is irrelevant. What is relevant is the actual energy of the primary electrons because of the dependence on that energy of the cross section for ionization by electron impact. For an electron in a core level of binding energy E_B, this dependence increases steeply with primary energy above E_B, passes through a maximum about 3 – 5 times E_B, and then decreases to a fairly constant plateau. It is illustrated in Figure 18, in which various theoretical and experimental cross sections are shown for ionization of the Ni K shell, from Casnati et al. [138]. The implication of this dependence is that for efficient ionization of a particular core level, the primary energy should be about five times the binding energy of an electron in that level. Since in most samples for analysis, several elements are found in the surface region with core-level binding energies extending over a large range, choice of a primary energy that is sufficiently high to ionize all the core levels efficiently is advisable. Hence for *conventional AES*, primary energies are typically in the range 3 – 10 keV. In *scanning Auger microscopy* (SAM), much higher primary energies are used, in the range of 25 – 50 keV, because in this version of AES as small an electron spot size must be achieved on the sample as possible, and the required focusing can be effected only at such energies.

For the primary energy range 3 – 10 keV used in conventional AES, the electron emitter is thermionic, usually an LaB_6 or a tungsten cathode, and focusing of the electron beam is carried out electrostatically. Typically, such an electron source would be able to provide a spot size on the specimen of about 0.5 µm at 10 keV and a beam

current of about 10^{-8} A. The beam can normally be rastered over the specimen surface, but such a source would not be regarded as adequate for SAM. Sources for SAM may be of either the thermionic or the field-emission type, the latter being particularly advantageous in achieving minimum spot sizes since it is a high-brightness source. Focusing is performed electromagnetically, and at optimum performance a modern electron gun for SAM would be capable of a spot size of 15 nm at 30 keV and a beam current of about 10^{-10} A. The beam is rastered over the surfaces at scan rates variable up to TV rates, with the dimensions of the scanned area variable as well.

Figure 18. Electron impact ionization cross section for the Ni K shell, as a function of reduced electron energy U [138] $U = E_P/E_K$, E_P being the primary electron energy and E_K the binding energy of the K shell
a) Experimental points; b) Semiempirical or theoretical curves

2.3.2.3. Electron Energy Analyzers

An electron energy analyzer still often applied in AES is the cylindrical mirror analyzer (CMA). In the CMA shown schematically in Figure 19, two cylinders of radii r_1 (inner) and r_2 (outer) are accurately positioned coaxially. Annular entrance and exit apertures are cut in the inner cylinder, and a deflection potential $-V$ is applied between the cylinders. Electrons leaving the sample surface at the source S with a particular energy E on passing into the CMA via the entrance aperture are then deflected back through the exit aperture to the focus F. For the special case in which the acceptance angle $\alpha = 42.3°$, the first-order aberrations vanish, and the CMA becomes a second-order focusing device. The relationship between the electron energy E and the deflection potential is then

$$E/\mathrm{eV} = 1.31/\ln(r_2/r_1) \tag{2.11}$$

As in the CHA, therefore, scanning the deflection potential $-V$ and recording the signal as a function of electron energy provide the distribution in energy of electrons leaving the sample surface.

Figure 19. Schematic of a cylindrical mirror analyser (CMA)

If the angular spread of the acceptance angle is $\delta\alpha$, then the relative energy resolution of the CMA is

$$\Delta E/E = 0.18w/r_1 + 1.39\,(\delta\alpha)^3 \tag{2.12}$$

where w is the effective slit width. For a typical angular spread $\delta\alpha$ of ca. 6°, w can be replaced by the source size (i.e., the area on the sample from which electrons are accepted). The source size is very small, because of the focused primary beam, and the important property of the CMA is therefore its very high transmission, arising from the large solid angle of acceptance; for a $\delta\alpha$ value of ca. 6°, the transmission is about 14 %.

Conventionally, Auger spectra are presented as the differentiated energy distribution $\mathrm{d}N(E)/\mathrm{d}E$, rather than in the undifferentiated form $N(E)$ used in XPS. By differentiating, the visibility of Auger features is enhanced, as demonstrated in Figure 20, in which the differentiated spectrum from boron is shown above the corresponding $N(E)$ spectrum. The $N(E)$ distribution is nowadays recorded digitally, and the differentiation is carried out by computer. However, with the rapid improvement in the signal-to-noise characteristics of detection equipment, the trend in presenting Auger spectra is increasingly toward the undifferentiated $N(E)$ distribution.

Note from Figure 20 that although the true position of the boron KLL Auger peak in the $N(E)$ spectrum is at 167 eV, the position in the $dN(E)/dE$ spectrum is taken for purely reasons of convention to be that of the negative minimum, i.e., at 175 eV.

Figure 20. Secondary electron distribution from boron a) In the $N(E)$ mode; b) – d) In the $dN(E)/dE$ mode, whereby the differentiation reveals the plasmon satellites

2.3.3. Spectral Information

As stated above, the range of primary energies used typically in conventional AES is 3 – 10 keV, and the ionization cross section passes through a maximum at 3 – 5 times the binding energy of an electron in the ionized core level. Therefore the core levels that can be ionized efficiently are limited. K-shell ionization efficiency is adequate up to $Z \approx 14$ (silicon), L_3 up to $Z \approx 38$ (strontium), M_5 up to $Z \approx 76$ (osmium), and so on (for the much higher primary energies used in SAM, the ranges are correspondingly extended). This means that in various regions of the periodic table, characteristic Auger transitions occur that are most prominent under typical operating conditions.

Figures 21, 22, 23 show some of these prominent Auger features. They have all been taken from [139], and recorded using a CMA, in the differential distribution. Examples of the KLL Auger series are shown in Figure 21, of the LMM series in Figure 22, and of the MNN series in Figure 23. In the KLL series the most prominent feature is a single peak arising from the $KL_{2,3}L_{2,3}$ transition, with minor features from other Auger transitions to lower energy. The LMM series is characterized by a triplet arising from $L_3M_{2,3}M_{2,3}$, $L_3M_{2,3}M_{4,5}$, and $L_3M_{4,5}M_{4,5}$ transitions in ascending order of kinetic energy, with another intense peak, the $M_{2,3}M_{4,5}M_{4,5}$, appearing at very low energy (e.g., 50 eV for iron). Note that AES transitions involving electrons in valence band levels are often written with a V rather than the full symbol of the level. Thus $L_3M_{2,3}M_{4,5}$ and $L_3M_{4,5}M_{4,5}$ would often appear as $L_3M_{2,3}V$ and L_3VV, respectively, and similarly $M_{2,3}M_{4,5}M_{4,5}$ as $M_{2,3}VV$. In Figure 22 the increase in intensity of the L_3VV peak relative to the other two upon going from chromium to iron is due to the progressive increase in the electron density in the valence band. The characteristic doublet seen in the MNN series arises from the $M_{4,5}N_{4,5}N_{4,5}$ transitions, in which the doublet separation is that of the core levels M_4 and M_5. The characteristic doublet seen in the MNN series arises from the $M_{4,5}N_{4,5}N_{4,5}$ transitions, in which the doublet separation is that of the core levels M_4 and M_5.

Chemical effects in Auger spectra are quite commonly observed, but they are difficult to interpret compared to those in XPS since additional core levels are involved in the Auger process. Some examples of the changes to be seen in the KLL spectrum of carbon in different chemical environments are given in Figure 24 [140–142]. Such spectra are typical components of data matrices (see Section 2.1.4.2) derived from AES depth profiles (see below).

Associated with prominent features in an Auger spectrum are plasmon loss features, as are also associated with photoelectron peaks in an XPS spectrum. Plasmon energy losses arise from excitation of modes of collective oscillation of the conduction electrons by outgoing secondary electrons of sufficient energy. Successive plasmon losses suffered by the backscattered primary electrons can be seen in both the $N(E)$ and the $dN(E)/dE$ spectra of Figure 20, from boron. The same magnitude of plasmon loss, $\approx$27 eV, is also associated with the KLL Auger peak of boron. Plasmon losses are also present in Figures 21, 22, 23, 24, but they are difficult to disentangle from minor Auger features.

Figure 21. KLL Auger series characteristic of the light elements [139]

Figure 22. LMM and MMM Auger series in the middle of the first series of transition elements [139]

Another type of loss feature not often recorded in Auger spectra can also be seen in Figure 20, in the d$N(E)$/dE spectrum at 810 eV. This type arises from core-level ionization and forms the basis for the technique of core electron energy loss spectroscopy (CEELS). A primary electron interacting with an electron in a core level can cause excitation either to an unoccupied continuum state, leading to complete ionization, or to localized or partly localized final states, if available. Since the primary electron need not give up all its energy in the interaction, the loss feature appears as a step in the secondary electron spectrum, with a tail decreasing progressively to lower energies. Differentiation, as in Figure 20, accentuates the visibility. In that figure, the loss at 810 eV corresponds to the K-shell ionization edge of boron at about 190 eV.

2.3.4. Quantification and Depth Profiling

2.3.4.1. Quantification

If ionization of a core level X in an atom A in a solid matrix M by a primary electron of energy E_{p} gives rise to the current $I_{\mathrm{A}}(XYZ)$ of electrons produced by the Auger transition XYZ, then the Auger current from A is

$$I_{\mathrm{A}}(XYZ) = K\sigma(E_{\mathrm{p}},X)\,[1+r_{\mathrm{M}}(X,\alpha)]\,\bar{N}_{\mathrm{A}}\,\lambda_{\mathrm{M}}(E_{\mathrm{A}})\cos\theta \qquad (2.13)$$

where $\sigma(E_{\mathrm{p}}, X)$ is the cross section for ionization of level X by electrons of energy E_{p}; r_{M} the

Figure 23. MNN Auger series in the second series of transition elements [139]

backscattering factor that takes account of the additional ionization of X (binding energy E_{B}) by inelastic electrons with energies between E_{p} and E_{B}; α the angle of incident electron beam to surface normal; $\bar{N}_{\mathrm{A}}$ the atomic density of A averaged over depth of analysis; $\lambda_{\mathrm{M}}(E_{\mathrm{A}})$ the inelastic mean free path in matrix M containing A, at the Auger kinetic energy E_{A}; and θ the angle of Auger electron emission to surface normal.

Similarly to Equation (2.6), K is a constant of proportionality containing fixed operational parameters such as incident electron current density, transmission of the analyzer at the kinetic energy E_{A}, efficiency of the detector at the kinetic energy E_{A}, and the probability of the Auger transition XYZ.

The cross section for electron impact ionization was already mentioned in Section 2.3.2.2 in connection with electron sources, and various experimental and theoretical cross sections are shown in Figure 18 for the particular case of the K shell of nickel. The expression for the cross section derived by Casnati et al. [138] gives reasonably good agreement with experiment, with the earlier expression of Gryzinski [143] also being useful.

For the inelastic mean free path, Equation (2.10) given for XPS also applies.

The new factor in Equation (2.13) compared to Equation (2.6) for XPS is the backscattering factor r_{M}. Ichimura and Shimizu [144] have carried out extensive Monte Carlo calculations of the backscattering factor as functions of pri-

Figure 24. Examples of the effect of different chemical states on the KLL Auger spectrum of carbon [140–142] (SiC∗ and graphite∗ denote Ar^+-bombarded surfaces of SiC and graphite, respectively)

mary beam energy and angle of incidence, of atomic number and of binding energy, and a selection of their results for $E_p = 10$ keV at normal incidence is shown in Figure 25. The best fit of their results to experiment gives the following relationship:

$$r = \left(2.34 - 2.1Z^{0.14}\right) U^{-0.35} + \left(2.58Z^{0.14} - 2.98\right) \quad \text{for} \quad \alpha = 0^\circ$$

$$r = \left(0.462 - 0.777Z^{0.20}\right) U^{-0.32} + \left(1.5Z^{0.20} - 1.05\right) \quad \text{for} \quad \alpha = 30^\circ$$

$$r = \left(1.21 - 1.39Z^{0.13}\right) U^{-0.33} + \left(1.94Z^{0.13} - 1.88\right) \quad \text{for} \quad \alpha = 45^\circ \tag{2.14}$$

where Z is the atomic number and $U = E_p/E_B$.

Thus, as for XPS, in principle the average surface concentration $\bar{N}_A$ can be calculated from the measurement of the Auger current, according to Equation (2.13). Again, as in XPS, relative sensitivity factors are generally used. The Auger current I_A^∞ for the same transition *XYZ* in a standard of pure A is measured under the same experimental conditions as in the analysis of A in M, whereupon the ratio of the atomic concentrations is

$$\bar{N}_A / N_A^\infty = \frac{I_A\,(1+r_A)\,\lambda_A R_A^\infty}{I_A^\infty\,(1+r_M)\,\lambda_M R_M} \tag{2.15}$$

since the ionization cross section σ is the same for both standard and sample. Then, as in XPS, assuming nearly equal roughness factors $R_A^\infty \approx R_M$, Equation (2.15) can be reduced to

$$\bar{N}_A = S_A I_A \tag{2.16}$$

where

$$S_A = \frac{\bar{N}_A^{\infty}\,(1+r_A)\,\lambda_A}{I_A^{\infty}\,(1+r_M)\,\lambda_M} \tag{2.17}$$

where S_A is then the relative sensitivity factor. Normally, values of S_A are derived empirically or semiempirically. Tables of such sensitivity factors have been published by PAYLING [145] and by MROCZKOWSKI and LICHTMAN [146] for differential Auger spectra, and for the direct, undifferentiated spectra by SATO et al. [147]. A comprehensive discussion of the assumptions and simplifications involved and the corrections that should be applied is given in [18], [148]. Although modern Auger spectrometers detect the spectra in the undifferentiated mode, many workers still evaluate the spectra in the electronically differentiated mode, that is, using the peak-to-peak heights, so that changes in peak shapes due to changes in chemical bondings are not taken into account and quantification in AES is still not as accurate as that in XPS.

2.3.4.2. Depth Profiling

As in XPS, elemental distributions near the surface, but to depths greater than the analytical depth resolutions, are frequently required when using AES. Again, the universally employed technique is that of progressive removal of the surface by ion sputtering; again one has to be aware that the electron spectroscopic sampling depth corresponds roughly to the depth of the layer modified by preferential sputtering effects, and again the edges of the sputter crater should not contribute to the signal.

A variation on depth profiling that can be performed by modern scanning Auger instruments (see Section 2.4) is to program the incident electron beam to jump from one preselected position on a surface to each of many others in turn, with multiplexing at each position. This is called multiple-point analysis. Sets of elemental maps acquired after each sputtering step or each period of continuous sputtering can be related to each other in a computer frame-store system to derive a three-dimensional analysis of a selected micro volume.

2.3.5. Applications

Like XPS, the application of AES has been very widespread, particularly in the earlier years of its existence; more recently, the technique has been applied increasingly to those problem areas that need the high spatial resolution that AES can provide and XPS as yet cannot. Since data acquisition in AES is faster than in XPS, it is also employed widely in routine quality control by surface analysis of random samples from production lines of, for example, integrated circuits. Particularly in semiconductor industry, SIMS is a competing method. Note that AES and XPS on the one hand, and SIMS/SNMS on the other, both in depth-profiling mode, are complementary, the former gaining signals from the sputter-modified surface, and the latter from the flux of sputtered particles.

2.3.5.1. Grain Boundary Segregation

One of the original applications of AES, and still one of the most important, is the analysis of grain boundaries in metals and ceramics. Very small amounts of impurity or dopant elements in the bulk material can migrate under appropriate temperature conditions to the boundaries of the

grain structure and accumulate there. In that way the concentration of minor elements at the grain boundaries can become much higher than in the bulk, and the cohesive energy of the boundaries can be so altered that the material becomes brittle. Knowledge of the nature of the segregating elements and their grain boundary concentrations as a function of temperature can be used to modify fabrication conditions and thereby improve the strength performance of the material in service.

GORETZKI [149] has discussed the importance and the analysis of internal surfaces such as grain boundaries and phase boundaries, and given several examples. He emphasizes that to avoid ambiguity in interpretation of the analysis, the internal surfaces must be exposed by fracturing the material under UHV conditions inside the electron spectrometer. If this is not done, atmospheric contamination would immediately change the surface condition irrevocably. One of the examples from GORETZKI's paper is given in Figure 26, in which Auger spectra in the differential mode from fracture surfaces in the embrittled (Fig. 26 A) and unembrittled (Fig. 26 B) states of a 12 % Cr steel containing phosphorus as an impurity are compared. Embrittlement occurs when the steel is held at 400 – 600 °C for a long time. Note in the spectrum from the embrittled material not only the greatly enhanced phosphorus concentration at the grain boundary, but also increased amounts of chromium and nickel with respect to iron. By setting the analyzer energy first to that of the phosphorus peak, and then to that of the principal chromium peak, Auger maps could be recorded showing the distribution of phosphorus and chromium over the fracture surface. The two maps showed high correlation of the two elements, indicating association of phosphorus and chromium at the grain boundary, possibly as a compound.

More recent work [150], [151] on the above 12 % Cr steel deal with the enhanced appearance of phosphorus at the grain boundaries of embrittled material. Other high-chromium steels have also been investigated [152], [153]. REICHL et al. [154] investigated the temperature dependence of surface segregation of S and N in α-Fe. In an initial phase, S diffusion took place at the grain boundaries and displaced N at the surface at higher temperatures. Other applications in the study of grain boundary segregation in metals have included the effects of boron, zirconium, and aluminum on Ni_3Al intermetallics [155], the segregation of phosphorus and molybdenum to grain boundaries in the superalloy Nimonic PE16 as a function of aging treatment [156], and the enrichment of chromium carbide and chromium iron carbide at the grain boundaries in steel [157].

Application of AES to zirconia ceramics is described by MOSER et al. [158]. Elemental maps of Al and Si demonstrate the grain boundary segregation of small amounts of silica and alumina impurities in these ceramics.

2.3.5.2. Semiconductor Technology

With ever-increasing miniaturization of integrated circuits goes a need for the ability to analyze ever smaller areas so that the integrity of fabrication at any point on a circuit can be checked. This checking process includes not only microdetails such as continuity of components in the form of thin films and establishment of the correct elemental proportions in contacts, diffusion barriers, and Schottky barriers, but also the effectiveness of more macrotreatments such as surface cleaning. In all these types of analyses, depth profiling (see Section 2.3.4.2) is used extensively because, in general, elemental compositional information is required, not information about chemical state. As mentioned in Section 2.1.4.2, chemical-state information tends to become blurred or destroyed by ion bombardment.

Various materials have been prescribed as *diffusion barriers* to prevent one circuit material from diffusing into another (often Si) at the temperatures needed for preparation of certain components such as oxide films in integrated circuits. ZALAR et al. [159] studied the interdiffusion at the Al_2O_3/Ti interface. They covered Si(111) with TiN thin film as diffusion barrier, then with a 45 nm of polycrystalline Ti, and finally with 55 nm of amorphous Al_2O_3. The same samples were heated to different temperatures at a rate of 40 °C/min, and the interdiffusion processes were investigated by AES depth profiling. Figure 27 shows that oxygen from Al_2O_3 and, to a lesser extent, also Al migrate into the Ti layer. (The "N + Ti" intensity in the Ti layer is only due to Ti, while in the neighboring TiN layer the

Figure 26. Auger spectra from fracture surfaces of a 12 % Cr steel [149]
A) Embrittled state; B) Unembrittled state

N + Ti intensity belongs to Ti and N because of peak overlapping.) Control measurements indicate that oxygen does not stem from the outer gas phase. In the interface region a new phase consisting of α-Ti_3Al is formed and detected by selected-area electron diffraction. Such AES investigations are normally carried out in combination with other surface-analytical techniques, in this case additionally with XPS, XRD, TEM and electron diffraction. Another work dealing with the analysis of CVD W_xN films as barriers for Cu metallization was published by Hua Li et al. [160], using AES, as well as RBS, AFM, XRD, and TEM.

The nature of metallic contacts to compound semiconductors has also been an interesting problem. Ohmic contacts must be made to semiconducting surfaces, otherwise circuits could not be fabricated. However, during fabrication, excessive interdiffusion must not occur, since otherwise the electrical characteristics of the semiconductor cannot be maintained. Among the many studies of the reactions of metallizing alloys with compound semiconductors is that of Roberts et al. [161], who investigated the W – TiN – Ti – Si contact structure using a multispectral Auger microscope (MULSAM) and TEM. Especially for the detection of small particles and defects which may be present in the ULSI regime, an Auger electron spectrometer with high spatial resolution imaging capability was developed which allows the inspection of wafers up to 200 mm in diameter [162].

AES has also been used to study preferential sputtering of $TiSi_x$ for forming low-resistivity conductor films in ULSI devices [163], and the electromigration behaviour of Au – Ag films on SiO_2 by using AES, XPS, and AFM [164].

AES has also been applied to a study of the oxidation of copper in printed circuit boards [524], of sulfur passivation of GaAs [525], of cleaning of germanium and GaAs with hydrogen dissociated by a noble-gas discharge [526], and of segregation and corrosion of silver layers electroplated onto light emitting diode (LED) lead frames as part of the final packaging [527].

2.3.5.3. Thin Films and Interfaces

The nature of the interface formed between very thin metallic films and substrates of various types has been studied extensively by AES, just as it has by XPS (see Section 2.1.6.6). The degree and extent of interaction and interdiffusion can be established by AES with depth profiling, although chemical information is normally absent, but the development of the interface is usually studied by continuous recording of Auger spectra during film deposition. Zhu *et al.* [165] deposited Ti or Cr layers on diamond samples. The Ti – diamond or Cr – diamond specimens were annealed at 600 °C for 4 h during metallization. Figures 28 A and B show the depth profiles before and after annealing of a Ti – diamond specimen, and Figures 28 C and D show the Ti

LM_1M_4 Auger line shapes in the $N(E)$ mode and the C KLL line shape in the differentiated $dN(E)/dE$ mode at various depths. The unstructured Ti signal at the surface can be attributed to TiO_2 due to a smooth oxidation of the surface. But the majority of the layer consists of TiC. The formation of TiC is also recognizable by the strongly structured carbon line, which changes its shape with depth and glides into that of diamond. All these features are consistent with the existence of TiC, indicating complete metallization.

Figure 27. AES sputter depth profiles of the α-Al_2O_3 – Ti thin-film structure on a smooth Si substrate covered with a TiN thin-film diffusion barrier
A) As-deposited; B) After heating to 500 °C; C) After heating to 580 °C [159].

Other interesting thin-film studies using AES have included the growth of platinum on TiO_2- and SrO-terminated $SrTiO_3$ (100) single-crystal substrates [166], of epitaxial niobium films on TiO_2 (110) [167], the interaction of copper with rhenium (0001) surface [168], and the characterization of radio-frequency sputtered TiN films on stainless steel [169].

A multilayer-type structure, probably due to cords in the molten zone between single arc sprayed (0.25 MPa) Ni droplets and a steel substrate were found in AES point depth profiles [170]. This particular arc-spraying condition proved to yield the best adhesion. Plasma-sprayed Al_2O_3 layers separated from pre-oxidized Ni Substrate exhibited a micrometer-thick NiO layer on the substrate-sided face and micrometer-deep oxide interdiffusion [171]. Also in this case, AES point depth profiling substantiated technological assumptions on adhesion mechanisms.

2.3.5.4. Surface Segregation

The surface composition of alloys, compounds, and intermetallics may change profoundly during heat treatment as a result of segregation of either or both constituent and impurity elements. Surface enhancement may also occur through chemical forces during oxidation or other reaction. The mechanism of segregation is similar to that of grain boundary segregation already discussed, but of course at the free surface material is much more likely to be lost through reaction, evaporation, etc., so that excessive continued segregation can change the bulk properties as well as those of the surface. Nearly all such studies have been carried out on metals and alloys, and AES has been applied to the problem almost from its inception.

Sometimes the segregation of metallic and nonmetallic elements together to surfaces can result in the formation of surface compounds, as demonstrated by Uebing [172], [173]. He heated a series of Fe – 15 % Cr alloys containing either 30 ppm nitrogen, 20 ppm carbon, or 20 ppm sulfur to 630 – 800 °C and obtained the typical Auger spectra shown in Figure 29. In each case an excess of both chromium and the nonmetal occurs in the spectrum, over that expected if the bulk concentration were maintained. The fine structure of the nitrogen and carbon KLL spectra is characteristic of nitride and

Figure 28. Depth profiles of a Ti – diamond layer before (A) and after annealing (B) at 600 °C for 4 h [165]. Auger line shapes of Ti LM_1M_4 (C) and C KLL (D) at various depths.

carbide, respectively. Hence, the co-segregation of chromium with nitrogen and with carbon has led to the formation of surface nitrides and carbides.

Song et al. [174] investigated surface segregation in $Ni_{0.65}Nb_{0.35}$ up to 500 °C and 0.1 MPa O_2 atmosphere. Below 100 °C, Nb segregated to the surface with formation of Nb_2O_5. At 300 °C and above, Ni segregated to the surface as Ni and NiO. This inverse segregation can be explained by different diffusion speeds of O and Ni in the Nb_2O_5 layer formed at the surface.

Other investigations involving AES, often with depth profiling, deal with the surface segregation of Ag in Al – Ag (4.2 %) [175], of Sn in Cu and formation of superficial Sn – Cu alloy [176], of Mg in Al – Mg alloys [177], and of Sb in Fe – Sb (4 %) alloy [178]. Note the necessity to disriminate segregation, that is, original sample properties, from the artifact of preferential sputtering.

2.4. Scanning Auger Microscopy (SAM)

If an incident electron beam of sufficient energy for AES is rastered over a surface in a manner similar to that in a scanning electron microscope (SEM), and if the analyzer is set to accept electrons of Auger energies characte ristic of a particular element, then an *elemental map or image* is again obtained, similar to XPS with the Quantum 2000 (see Section 2.1.2.5).

An example is shown in Figure 30 [179]. The surface was that of a fractured compact of SiC to which boron and carbon had been added to aid the sintering process. The aim of the analysis was to establish the uniformity of distribution of the additives and the presence or absence of impurities. The Auger maps show not only very nonuniform distribution of boron (Fig. 30 A) but also a strong correlation of boron with sodium (Fig. 30 C), and a weaker correlation of boron with potassium (Fig. 30 B). Point analyses at A

and B marked on the images reveal the presence of sulfur and calcium in some areas as well. In this case the sintering process had not been optimized.

Dedicated *scanning auger microscopes* with ultimate spatial resolution have been developed towards the smallest possible spot size and still acceptable Auger signal-to-noise ratio obtained within tolerable acquisition time. Electron guns used for SAM employ electromagnetic focusing. Since focusing electrons of low energy into a small spot is difficult, energies used in SAM are in the range of 25 – 50 keV, with beam currents on the order of 1 nA or less and a minimum spot size of about 15 nm.

a) Nitride; b) Carbide; c) Sulfide

2.5. Other Electron-Detecting Techniques

2.5.1. Auger Electron Appearance Potential Spectroscopy (AEAPS)

Due to the emission of an Auger electron as an alternative to soft X-ray photons, the total secondary electron yield will show an increase as an ionization threshold is crossed. It is the total secondary yield that is monitored in AEAPS, in a rather simple experimental arrangement. The secondary current arises not just from the Auger electrons themselves, but also from inelastic scattering of Auger electrons produced at greater depths below the surface. Since the yield change is basically a measure of the probability of excitation of a core-level electron to an empty state above the Fermi level, the fine structure above the threshold will be similar to that seen in SXAPS. One of the problems in AEAPS is that of a poorly behaved background, which means that SXAPS is preferred.

2.5.2. Electron Energy Loss Methods

2.5.2.1. Electron Energy Loss Spectroscopy (EELS) and Core-Electron Energy Loss Spectroscopy (CEELS)

The techniques of EELS and CEELS can be discussed together because they use the same experimental arrangement, basically that of conventional AES. A beam of primary electrons interacts with electrons in surface atoms, and the energy losses suffered by the primary electrons are measured by recording the appropriate part of the secondary electron spectrum in an energy analyzer. In *EELS* the losses are relatively small, being due to the energies required to stimulate electronic transitions within the valence band of the solid, and collective oscillations of the conduction electrons (plasmon oscillations). For each solid the plasmons have energies characteristic of the bulk structure and of the surface structure, the surface plasmon having theoretically an energy lower than that of the bulk by a factor of $2^{1/2}$. In *CEELS* the primary electron interacts with a core level, usually but not always leading to ionization, and the losses are in general much greater than in ELS. Thus in EELS the observed losses are normally within 30 – 50 eV

Figure 30. SAM map of fractured SiC after sintering with B addition [179]
a) – d) Elemental maps in boron, potassium, sodium, and oxygen, respectively; E), F) Point analyses at points ○A and ○B, respectively

of the primary energy, whereas in CEELS they may be several hundred electronvolts away.

Since all loss features are by definition associated with the primary energy, features characteristic of the surface can be compared to those of the bulk by variation of the primary energy (i.e., by effectively varying the electron escape depth). Such variation is standard practice in ELS, in which the range of primary energies used is typically 100 – 1000 eV. In CEELS, in contrast, although the relation between primary energy and escape depth still applies, the primary energy must be high enough to ionize the core level with adequate efficiency, as discussed in Section 2.3.2.2 for AES. Thus for CEELS the primary energy range would be the same as for conventional AES (i.e., 2 – 5 keV).

CEELS has been applied more to the study of core-electron excitation to localized final atomic states than to excitation to the continuum (i.e., complete ionization). Core-level ionization thresholds can in principle be used to obtain an elemental composition, but the spectral features are weak, and the analysis is performed far better by XPS. Nevertheless, where shallow, highly localized final states exist, CEELS has been able to provide useful information.

2.5.2.2. High-Resolution Electron Energy Loss Spectroscopy (HREELS)

In this technique, electrons of very low primary energy, typically 3 – 5 eV, are directed at a surface carrying adsorbed molecules. As the electrons approach closely enough, they interact with the molecular field and are reflected (i.e., scattered) having lost discrete amounts of energy corresponding to characteristic vibrational frequencies, either within the molecules or between the molecules and the surface. Analysis of the scattered electron energy distribution then reveals the energy losses, and hence the vibrational frequencies. If the molecules are attached to the surface only loosely (*physisorption*), many of the characteristic vibrations within a molecule are similar to those observable in the gas phase. These consist of various stretching and deformation modes of vibration. In addition, other modes appear as a result of attachment to the surface. In the gas phase a molecule can translate and rotate freely, but if one end is fixed to a surface it can no longer do so, and therefore certain translational and rotational modes of vibration become observable that cannot be observed in the free molecule. Should the molecule be attached strongly to the surface (*chemisorption*), perhaps with the loss of reactive groups, and certainly with a transfer of electronic charge, then the characteristic free-molecule stretching vibrations can become so distorted that they no longer resemble those seen in the gas phase. Thus the HREELS spectrum from a complex polyatomic molecule adsorbed on a surface can itself be very complex and contain a great deal of information concerning the way in which the molecule has reacted with the surface and also with neighboring molecules. The orientation of the molecule can often be deduced as well, particularly when HREELS is used with other techniques such as LEED, UPS, and TDS.

Because the energy widths of the characteristic vibrational energies are small, < 0.1 meV, for optimum energy resolution one must achieve as narrow an energy spread in the incident electron beam as possible. In all HREELS equipment, therefore, extreme measures are taken to reduce the spread in a variety of ways. Most importantly, the incident electrons are energy selected in a monochromator that is basically an electron energy analyzer used in reverse. Monochromators properly constructed can reduce the energy spread in the incident beam to 2 – 3 meV, but to maintain that width in the beam at the sample surface requires the complete elimination of stray magnetic and electrostatic fields around the sample. Thus very careful screening of the entire HREELS analytical arrangement is necessary. Many experiments are also carried out at low temperature to reduce the thermal broadening of characteristic vibrations.

2.5.3. Diffraction Methods

2.5.3.1. Low-Energy Electron Diffraction (LEED)

Both LEED and RHEED are probes of surface structure that depend on the existence of long-range order of periodic structure in the surface. They do not provide compositional information and are always used along with other techniques such as AES that can analyze for composition.

Low-Energy Electron Diffraction. In LEED a collimated and monoenergetic beam of electrons of variable energies between about 20 and 1000 eV strikes the surface of a single crystal at normal incidence. An energy selector, almost universally consisting of a set of spherical grids centered on the specimen, repels all secondary electrons except those elastically scattered (i.e., those at the primary energy). The elastically scattered electrons are then accelerated to a spherical fluorescent screen, on which the diffraction pattern can be seen. Measurement of diffraction spot intensity can be made either with a photometer or with a movable Faraday cup.

Diffraction occurs due to the wave nature of electrons. The waves represented by the incident electron beam interfere as a result of reflection by a periodic crystal structure in such a way that the reflected beams are anisotropic in direction and are in fact concentrated in certain directions related directly to the crystal structure. Where the reflected beams are intercepted by the fluorescent screen, a spot pattern results. The purely geometric relationship between the observed pattern and the surface structure is governed by the well-known Bragg equation, which connects the directions of the interference maxima with the surface lattice spacing and the primary energy. The observed diffraction pattern is a direct representation of the reciprocal lattice of the surface. Since the electron wavelength is of the same order of magnitude as the surface lattice spacing, only a few diffraction spots appear at low primary energies (<100 eV), but as the energy is increased, further spots appear and move with energy toward the normally deflected (i.e., undiffracted) beam. At the same time, the existing spots vary in intensity, appearing and disappearing on the fluorescent screen as they move with energy inward along radial directions.

The simple geometric, or kinematic, representation of the LEED pattern is valid only for scattering from those atoms actually in the surface (i.e., exposed to the incident electron beam). However, the incident beam has a finite depth of penetration, which of course increases with increasing energy; therefore the periodicity of the crystal normal to the surface must also be taken into account. This can be explored by recording the intensity of a particular diffraction spot as a function of primary electron energy (i.e., wavelength). The normally reflected beam will have intensity maxima due to the vertical periodicity, which are called primary Bragg peaks if the maxima are predicted by the Bragg equation, and secondary Bragg peaks if they are not. The latter are caused by multiple scattering effects, which can be accounted for only in a dynamic theory of scattering. The latter is complicated and can be applied only by using computer simulation, in which a feasible structure for the surface is guessed, from which diffraction intensities are calculated and compared with experiment. In this way a surface structure can be solved completely, but ambiguities cannot be eliminated in most cases.

2.5.3.2. Reflection High-Energy Electron Diffraction (RHEED)

The same diffraction mechanism is used in RHEED, but the experimental arrangement is quite different, and the observed pattern differs as well. Much higher primary electron energies are used than in LEED, in the range of 15 – 30 keV, and the primary beam is directed onto the crystal surface at near grazing incidence, at angles $< 5°$. As a result, the diffraction pattern is a mixture of spots and streaks. For such low angles of incidence the surface must be very smooth and flat, which is a limitation of the technique, but the requirement also means that any growth feature appearing above the original surface is easily identified since it produces its own characteristic diffraction pattern in transmission. In a variation of RHEED, the angle of the primary beam is varied backward and forward through a few degrees, which is called *rocking*, by analogy with the rocking patterns recorded in X-ray diffraction. Analysis of surface structure, with the assistance of sophisticated data processing, is less ambiguous when the rocking variation is used.

RHEED has also been used in basic studies, although to a far lesser extent because of its inherent restrictions, but in recent years it has found technological application as well. Semiconductor surfaces are usually flat, and epitaxial films grown on them are often flat as well. In those circumstances RHEED has proved to be a useful tool in the quality control of the structural condition of a semiconductor substrate and

then of the perfection or otherwise of any films or layers grown or deposited on it. Thus each of the large UHV systems built for molecular beam epitaxy (MBE) contains a RHEED diagnostic system as one of the standard inspection techniques of the epilayer during and after growth.

2.5.4. Ion-Excitation Method

2.5.4.1. Ion (Excited) Auger Electron Spectroscopy (IAES)

Auger emission following creation of a core hole by electron or photon irradiation has been described under AES and XPS. Incident ions can also create core holes, so that Auger emission as a result of ion irradiation can also occur, giving rise to the technique of IAES. The ions used are normally noble-gas ions, but protons and α particles have occasionally been used as well. In addition to the normal Auger features found in AES and XPS spectra, peaks are found in IAES spectra arising from Auger transitions apparently taking place in atoms or clusters sputtered from the surface. These peaks do not always coincide with those found in gas-phase excitation, and others are found that are not present in gas-phase measurements. Because of the complexity of the spectra, IAES cannot be used directly as an analytical technique, but it is very useful in basic physics experiments that study Auger processes occurring in excited atoms.

2.5.4.2. Ion-Neutralization Spectroscopy (INS)

The technique of INS is probably the least used of all those described here, because of experimental difficulties, but it is also one of the physically most interesting. Ions of He^+ of a chosen low energy in the range 5 – 10 eV approach a metal surface and within an interaction distance of a fraction of a nanometer form ion – atom pairs with the nearest surface atoms. The excited quasi molecule so formed can deexcite by Auger neutralization. If unfilled levels in the ion fall outside the range of filled levels of the solid, as is the case for He^+, then an Auger process can take place in which an electron from the valence band of the solid fills the core hole in the ion and the excess energy is given up to another valence electron, which is then ejected. Since either of the valence electrons can come from anywhere within the valence band, the observed energy spectrum reflects the local density of states at the solid surface, but is a self-convolution of the LDOS and of transition probabilities across the valence band. The technique of INS requires a complex mathematical treatment for deconvolution of the spectra. Because the technique of STS is also capable of extracting the LDOS, the results from INS and STS should be comparable, but such a comparison does not seem to have been attempted yet.

2.5.4.3. Metastable Quenching Spectroscopy (MQS)

MQS is in a sense an extension of INS. Instead of He^+ ions, helium atoms in metastable states are used in the incident beam, at the same low energies. The excited singlet state $He*(2^1S_1)$ has an energy of 20.62 eV and a lifetime of 2×10^{-2} s, and so is suitable. It is produced by expanding helium gas at high pressure through a nozzle into a cold cathode discharge sustained by combined electrostatic and magnetic fields. The high fields prevent ions and fast neutrals from leaving the discharge, and the beam is then nearly all $He*(2^1S_1)$. As the metastable ion approaches the surface, either of two mechanisms can lead to deexcitation, both resulting in Auger emission similar to INS. If the excited level in the atom can resonate with empty states at the Fermi level of the surface, electron transfer from the atom to the surface can occur, leading to resonance ionization of the helium atom. Auger neutralization then takes place as in INS, and the resultant spectrum is again a self-convolution of the LDOS. If, however, the excited level cannot resonate with empty surface states, then direct Auger deexcitation can occur, in which the hole in the inner shell of the metastable helium atom is filled from a surface state of the sample, followed by ejection of the excited electron from the helium atom. The process is also called Penning ionization. In the latter process, only one electron is ejected, and the resultant spectrum is thus an unconvoluted reflection of the LDOS.

2.5.5. Inelastic Electron Tunneling Spectroscopy (IETS)

IETS is unique in that it is entirely surface specific, but does not require a vacuum environment and has almost never been performed in UHV. Its principle is relatively simple. If two metals are separated by a thin (≈3 nm) insulating layer, and a voltage is applied across them, electrons can tunnel from one to the other through the insulator, and if no energy is lost by the electrons, the process is known as elastic tunneling. However, should discrete impurity states occur in the interface between either metal and the insulator, or molecules exist in such an interface that possess characteristic vibrational energies, then the tunneling electron can give up some of this energy either to the state or to the vibrational mode, before reaching the other metal. This is called inelastic tunneling. Obviously, the applied voltage must be greater than the state or vibrational energies. If the current across the metal – insulator – metal sandwich is recorded as a function of applied voltage, the current increases as the threshold for each state or vibrational mode is crossed. The increases in current are in fact very small, and for improved detectability, the current is double differentiated with respect to voltage, thereby providing in effect a vibrational spectrum that can be compared directly with free-molecule IR and Raman spectra.

The metal – insulator – metal sandwich is known as a tunnel junction, and its preparation is all-important. The standard junction consists of an aluminum strip ca. 60 – 80 nm thick and 0.5 – 1.0 mm wide deposited in a very good vacuum onto scrupulously clean glass or ceramic, the surface of the strip then being oxidized either thermally or by glow discharge. The resultant oxide layer is extremely uniform and about 3 nm thick. Introduction of adsorbed molecules onto the oxide layer, or "doping" as it is called, is then effected either by immersion in a solution followed by spinning to remove excess fluid, or by coating from the gas phase. The final stage in preparation is deposition of the second metal (invariably lead) of the sandwich; this deposition is carried out in a second vacuum system (i.e., not the one used for aluminum deposition), the final thickness of lead being about 300 nm, and the width of the lead strip being the same as that of the aluminum strip. The reason for using lead is that all IETS measurements are carried out at liquid-helium temperature, 4.2 K, to optimize the energy resolution by reducing the contribution of thermal broadening to the linewidth, and of course lead is superconducting at that temperature.

Normally not one, but several, junctions are fabricated simultaneously, since the likelihood of junction failure always exists. After fabrication the electrical connections are made to the metal electrodes, the junctions are dropped into liquid helium, and measurements are commenced at once.

Although insulators other than aluminum oxide have been tried, aluminum is still used almost universally because it is easy to evaporate and forms a limiting oxide layer of high uniformity. To be restricted therefore to adsorption of molecules on aluminum oxide may seem like a disadvantage of the technique, but aluminum oxide is very important in many technical fields. Many catalysts are supported on alumina in various forms, as are sensors, and in addition the properties of the oxide film on aluminum metal are of the greatest interest in adhesion and protection.

3. Ion Detection

3.1. Secondary Ion Mass Spectrometry

3.1.1. Static Secondary Ion Mass Spectrometry (SSIMS)

SSIMS emerged as a technique of potential importance for surface analysis owing to the work of Benninghoven et al. in Münster [180] during the late 1960s and early 1970s (i.e., at roughly the same time as AES). The prefix "static" was added to distinguish the technique from "dynamic" SIMS, the difference between the two lying in the incident current densities used: on the order of < 1 nA/cm^2 for SSIMS but much higher for dynamic SIMS. With this low primary ion dose, spectral data can be generated on a timescale that is very short compared to the lifetime of the surface layer (typically a surface destruction of < 1 %).

Together with XPS and AES, SSIMS ranks as one of the principal surface analytical techniques. Since its sensitivity for elements greatly

exceeds that of the other two techniques and a large amount of chemical information is available, its use is rapidly expanding in many application fields.

3.1.1.1. Principles

A beam of positive ions bombards a surface, and the resulting interactions cause the emission of a variety of types of secondary particles, including secondary electrons, Auger electrons, photons, neutrals, excited neutrals, positive secondary ions, and negative secondary ions. SSIMS is concerned with the last two of these, *positive* and *negative secondary ions*. The emitted ions are analyzed in a mass spectrometer, which results in positive or negative mass spectra that consist of parent and fragment peaks characteristic of the surface. The peaks may be identifiable as arising from the substrate material itself, from contamination and impurities on the surface, or from deliberately introduced species adsorbed on the surface.

When a heavy energetic particle such as an argon ion (typically 1 – 15 keV) strikes a surface, it will not be stopped short by the first layer of atoms, but continues into the surface until it comes to a halt as a result of energy lost in atomic and electronic scattering. Along its way, the ion displaces some atoms from their normal positions in the solid structure, which as they recoil displace others, which displace additional atoms, and so on, resulting in a complex sequence of collisions. Depending on the energy absorbed in an individual collision, some atoms are permanently displaced from their normal positions, whereas others return elastically after temporary displacement. This sequence is called a collision cascade and is illustrated schematically, along with some other processes, in Figure 31. As the cascade spreads out from the path of the primary ion, its effect may eventually reach atoms in the surface layer, and with enough kinetic energy left, bonds may be broken so that material leaves the surface in form of neutral or ionized atoms or clusters. The resulting secondary particle emission is of low energy (peak of energy distribution between 5 and 10 eV) with over 95 % of the secondary particles originating from the two top monolayers of the solid. Therefore, detecting these ionized particles directly with a mass spectrometer results in very high surface sensitivity.

The theoretical aspect of the collision cascade is given by SIGMUND's collision cascade model [181] which explains much about the parameters involved in the removal of material from a surface by sputtering, although it cannot predict the degree of positive or negative ionization of the material. A unified theory of secondary ion formation in SSIMS does not yet exist, although many models have been proposed for the process. Since the secondary ion yield (i.e., the probabilities of ion formation) can vary by several orders of magnitude for the same element in different matrices, or for different elements across the periodic table, lack of a means of predicting ion yield in a given situation limits both interpretation and quantification. Some theoretical and semitheoretical models have successfully made predictions for a very restricted range of experimental data, they fail when extended further. The most important theoretical models are briefly addressed in Section 3.1.2.1; for further information see, e.g., [182].

3.1.1.2. Instrumentation

The instrumentation for SSIMS can be divided into two parts: (1) the primary ion source in which the primary ions are generated, transported, and focused towards the sample, and (2) the mass analyzer, in which sputtered secondary ions are extracted, mass-separated, and detected.

3.1.1.2.1. Ion Sources

Two types of ion source are particularly suited for SSIMS. The first produces *positive noble gas ions* (usually argon) either by electron impact (EI) or in a plasma created by a discharge (see Fig. 48). The ions are then extracted from the source region, accelerated to the chosen energy, and focused in an electrostatic ion optical column. More recently, it was shown that the use of primary polyatomic ions such as SF_5^+, created in EI sources, could enhance the molecular secondary ion yield by several magnitudes [183], [184]. Cesium ions also are sometimes used to enhance the secondary ion yield of negative elemental ions, as well as that of some polymer

Figure 31. Schematic of the sputtering process

fragments [185]. They are produced by surface ionization with an extraction technique similar to that of EI sources.

Argon ion guns of the electron-impact type operate in the energy range of 0.5 – 10 keV with a 1 – 10 µA dc current, providing optimum spot sizes on the surface of about 10 µm. Discharge-type argon ion guns, often using the duoplasmatron arrangement, operate at up to 15 keV, with currents variable up to 20 µA and, depending on the particular focusing lens system used, providing spot sizes down to about 2 µm.

The second type of ion gun produces *positive ions from a liquid metal* (almost always gallium) in the manner shown schematically in Figure 32 [186]. A fine needle (f; tip radius ≈ 5 µm) of refractory metal passes through a capillary tube (d) into a reservoir of liquid metal (e). The liquid is drawn up through the tube over the needle tip by capillary action. Application of 10 – 30 keV between the needle and a nearby extractor electrode (b) draws the liquid up into a cusp (Taylor cone) through the combined forces of surface tension and electrostatic stress. Ions are formed in the region just above the cusp, which are then accelerated through an aperture in the extractor and focused through an ion optical column onto the sample surface. Gallium is mainly used as the liquid metal because its melting point of 35 °C allows it to remain liquid at room temperature; other metals such as In and Au have been tried but require heating of the reservoir. Because ion production occurs in a very small volume, *gallium liquid metal ion sources* (LMIS) have a very high brightness (ca. 10^{10} A m^{-2} Sr^{-1}). As a result, the ion beam may be focused to a fine spot, resulting in a spot size of 0.2 µm at 8 – 10 keV, which is reduced to about 20 nm at 30 keV.

All ion gun optical columns provide deflection plates for scanning the ion beam over areas adjustable from many square millimeters to a few square micrometers. They have been adapted for pulsing by the introduction of deflection plates which rapidly sweep the beam across an aperture. By applying an ion beam bunching technique, ion pulses of less than 1 ns width can be produced.

3.1.1.2.2. Mass Analyzers

To minimize surface damage, SSIMS mass spectrometers should be as efficient as possible in detecting the total yield of secondary ions from a surface. Also, to be able to separate elemental from molecular species, and molecular species from each other, the mass-resolving power, usually expressed as mass m divided by separable mass Δm should be very high. With this in mind, two types of mass spectrometers have been used: in early work mainly quadrupole mass filters

and, more recently, time-of-flight mass spectrometers.

Figure 32. Schematic of the design and operation of a liquid-metal ion source (LMIS) [186]
a) Metal ions; b) Extractor; c) Liquid-metal film; d) Capillary tube; e) Liquid metal; f) Needle

Quadrupole Mass Spectrometer. The quadrupole mass spectrometer has been in use for many years as a residual gas analyzer (with an ionizing hot filament), as well as in desorption studies and SSIMS. It consists of four circular rods, or poles, arranged so that they are equally spaced in a rectangular array and exactly coaxial (Fig. 33 [187]). Two voltages are applied to the rods, a dc voltage U_{dc} and an rf voltage ($U_{rf} \sim U_0 \cos\omega t$). When an ion with a certain mass-to-charge ratio m/q enters the space between the rods, it is accelerated by the electrostatic field, and for a particular combination of dc and rf voltages, the ion has a stable trajectory and passes to a detector. For other combinations of voltages, the trajectory diverges rapidly and the ion is lost either by hitting one of the poles or by passing between them to another part of the system. The mass resolution is governed by the dimensions of the mass spectrometer, the accuracy of its construction, and the stability and reproducibility of the ramped voltage. The quadrupole mass spectrometer is compact, does not require magnets, and is entirely ultrahigh vacuum compatible – hence its popularity. It does have disadvantages, however, in that its transmission (typically $< 1\,\%$) is very low and decreases with increasing mass number. Furthermore, it is a scanning instrument that allows only the sequential transmission of ions, all other ions being discarded. Hence, the information loss is very high.

Time-of-Flight Mass Spectrometer (TOFMS). Because the quadrupole mass spectrometer is unsuitable for the analysis of large molecules on surfaces or of heavy metals and alloys, the TOF mass spectrometer was developed for use in SSIMS by Benninghoven et al. [188]. In a TOF mass analyzer (Fig. 34), all sputtered ions are accelerated to a given potential V in the range of 2 – 8 keV, so that all ions possess the same kinetic energy. The ions are then allowed to drift through a field-free drift path of a given length L before striking the detector. According to the equation $(mL^2)/(2t^2) = qU_o$, light ions travel the fixed distance through the flight tube more rapidly than identically charged heavy ions. Thus, the measurement of the time t of ions with mass-to-charge ratio m/q provides a simple means of mass analysis with $t^2 = (mL^2)/(2qU_o) \propto m/q$. Because a very well defined start time is required for the flight time measurement, the primary ion gun must be operated in a pulsed mode to deliver discrete primary-ion packages [189]. Electric fields (e.g., ion mirrors [189], [190] or electrical sectors [191], [192]) are used in the drift path to compensate for different incident energies and angular distributions of the secondary ions. For good mass resolution ($m/\Delta m \approx 10\,000$), the flight path must be sufficiently long (1 – 1.5 m), and sophisticated high-frequency pulsing and counting systems must be employed to time the flight of the ion to within a nanosecond. A malor advantage of TOFMS is its ability to simultaneously detect of all masses of the same polarity. Raw data acquisition [193] allows the reconstruction of TOF-spectra for any ion species as a function of depth and lateral position.

The original TOF design [188] used pulsed beams of argon ions, but commercial development of LMIS has significantly extended the capabilities of the TOF system. The principle of LMIS operation allows the beam of $^{69}Ga^+$ and $^{71}Ga^+$ ions to be focused to a probe of 50 nm minimum diameter, while being pulsed at frequencies up to 50 kHz and rastered at the same time. Mass filtering selects either of the isotopes before the beam strikes the sample, unless isotopically enriched gallium is used. Operating an LMIS at beam currents of 10 – 100 pA,

Figure 33. Experimental arrangement for SSIMS used by Krauss and Gruen [187] employing a quadrupole mass spectrometer for mass analysis and a retarding-field analyzer for prior energy selection

opens up the possibility of performing scanning SSIMS and of producing secondary-ion images in selected masses. Pulsing of the ion source is achieved by rapid deflection of the ion beam across a small aperture, the pulse length being variable between 1 and 50 ns. The flight path length is 1.5 m, part of which includes an energy compensator (ion mirror) to ensure that all ions of the same mass, but of different energies, arrive at the same time. Secondary electron detectors (SED) allow topographical images produced by ion-induced secondary electrons to be generated; a low-energy electron flood gun (> 20 eV) can be used for charge compensation when an insulating sample is analyzed; a temperature-controlled sample holder permits SSIMS data to be obtained as a function of surface temperature (temperature-programmed SIMS, TP-SIMS).

With such a TOF-imaging SSIMS instrument, the useful mass range is extended beyond 10 000 amu; the mass resolution $m/\Delta m$ is ca. 10 000 with simultaneous detection of all masses; and within each image, all masses can be detected. The amount of data generated in a short time is enormous, and sophisticated data-acquisition systems are required to handle and process the data.

3.1.1.3. Quantification

By bombarding a surface consisting of species A with primary ions, the surface coverage of A is reduced. The A particle can be removed by desorption, by fragmentation in the case of molecular species, or by being driven into a deeper layer. The ratio of the number of sputtered particles to the number of primary ions is given by the disappearance yield $Y_{\mathrm{D}}(\mathrm{A})$:

$$Y_{\mathrm{D}}\,(\mathrm{A}) = \frac{\text{No. of sputtered } A}{\text{No. of primary ions}} \tag{3.1}$$

A quantity related to the disappearance yield for a particle of a species covering a solid surface with a surface density $\vartheta(\mathrm{A})$ is the disappearance cross section $\sigma_{\mathrm{D}}(\mathrm{A})$, which corresponds to the average area damaged by one primary ion impact:

$$\sigma_{\mathrm{D}}\,(\mathrm{A}) = \frac{Y_{\mathrm{D}}\,(\mathrm{A})}{\vartheta\,(\mathrm{A})} \tag{3.2}$$

The change in the surface density $\vartheta(\mathrm{A})$ with increasing primary ion fluence F_{PI} is given by:

$$\vartheta\left(\mathrm{A}, F_{\mathrm{PI}} = \vartheta\,(\mathrm{A})_0 \cdot \exp\left(-\sigma_{\mathrm{D}}\,(\mathrm{A})\,F_{\mathrm{PI}}\right)\right) \tag{3.3}$$

Some particles sputtered from the surface are neutral, while others are charged. Molecular particles can be emitted as intact molecules and as fragments. The probability for the desorption of A into the emission channel $\mathrm{X}_i^{\mathrm{q}}$ is given by the transformation probability $P(\mathrm{A} \rightarrow \mathrm{X}_i^{\mathrm{q}})$:

$$P\left(\mathrm{A} \rightarrow \mathrm{X}_i^{\mathrm{q}}\right) = \frac{\text{No. of emitted particles } \mathrm{X}_i^{\mathrm{q}}}{\text{No. of sputtered } A} \tag{3.4}$$

where i is an index distinguishing between the different emission channels, and q is the charge of the particle X_i, where $q = 0, \pm 1, \pm 2, \pm 3, \ldots$ The transformation probability for ionization cannot be easily measured because it strongly depends on matrix and concentration. In fact, it represents the principal obstacle in achieving proper quantification in SSIMS.

The average number of emitted particles $\mathrm{X}_i{}^{\mathrm{q}}$ per incident primary ion is given by the secondary ion yield $Y^{(\mathrm{q})}(\mathrm{X}_i^{\mathrm{q}})$:

$$Y^{(q)}\left(\mathrm{X}_i^{\mathrm{q}}\right) = \frac{\text{No. of emitted particles } \mathrm{X}_i^{\mathrm{q}}}{\text{No. of primary ions}} \tag{3.5}$$

For the detection of sputtered ions, the transmission $T(\mathrm{X}_i^{\mathrm{q}})$ of the mass spectrometer and the detection probability $D(\mathrm{X}_i^{\mathrm{q}})$ must be taken into account. Their product gives the probability of detecting one sputtered particle $\mathrm{X}_i^{\mathrm{q}}$. For a TOF mass spectrometer, $T(\mathrm{X}_i^{\mathrm{q}})$ typically is 10 – 100 %, and $D(\mathrm{X}_i^{\mathrm{q}})$ 10 – 50 %.

The number of detected particles per incident primary ion is given by the detected yield $Y(\mathrm{X}_i^{\mathrm{q}})$:

$$Y\left(\mathrm{X}_i^{\mathrm{q}}\right) = \frac{\text{No. of detected } \mathrm{X}_i^{\mathrm{q}}}{\text{No. of primary ions}} \tag{3.6}$$

An important quantity is the so-called useful yield $Y_{\mathrm{u}}(\mathrm{A}, \mathrm{X}_i^{\mathrm{q}})$:

$$Y_{\mathrm{u}}\left(\mathrm{A}, \mathrm{X}_i^{\mathrm{q}}\right) = \frac{\text{No. of detected } \mathrm{X}_i^{\mathrm{q}}}{\text{No. of sputtered } A} \tag{3.7}$$

The useful yield provides an overall measure of the degree to which the sputtered material is used for analysis. It is a quantity employed to estimate the sensitivity of the mass spectrometric method. Values of $Y_{\mathrm{u}}(\mathrm{A}, \mathrm{X}_i^{\mathrm{q}})$ for elements typically range from 10^{-6} to 10^{-2} in the case of TOF-SIMS. The number of sputtered particles A per incident primary ion (*sputtering yield*) can be measured from elemental and multielemental standards under various operational conditions and can therefore be estimated to reasonable accuracy for the material being analyzed by judicious interpolation between standards.

Since measuring A can be problematic, quantification is normally carried out by relative sensitivity factor (RSF) methods. If a species A on the surface is detected by means of the ion $\mathrm{X}_i^{\mathrm{q}}$, the ratio of the detected ion current $I_{\mathrm{A}}\mathrm{X}_i^{\mathrm{q}})$ to the primary ion current I_{PI} and the surface density $\vartheta(\mathrm{A})$ is called the practical sensitivity factor $S_{\mathrm{p}}[\mathrm{X}_i^{\mathrm{q}}(\mathrm{A})]$:

$$S_{\mathrm{p}}\left[\mathrm{X}_i^{\mathrm{q}}(\mathrm{A})\right] = \frac{I_{\mathrm{A}}\left(\mathrm{X}_i^{\mathrm{q}}\right)}{\vartheta(\mathrm{A})\, I_{\mathrm{PI}}} \tag{3.8}$$

The ratio of two practical sensitivity factors is called the RSF $S[\mathrm{X}_i^{\mathrm{q}}(\mathrm{A}), \mathrm{X}_i^{\mathrm{q}}(\mathrm{B})]$, which is independent of the primary ion current I_{PI}:

$$S\left[\mathrm{X}_i^{\mathrm{q}}(\mathrm{A}), \mathrm{X}_{i'}^{\mathrm{q}'}(\mathrm{B})\right] = \frac{S\left[\mathrm{X}_i^{\mathrm{q}}(\mathrm{A})\right]}{S\left[\mathrm{X}_{i'}^{\mathrm{q}'}(\mathrm{B})\right]} = \frac{I_{\mathrm{A}}\left(\mathrm{X}_i^{\mathrm{q}}\right)}{I_{\mathrm{B}}\left(\mathrm{X}_{i'}^{\mathrm{q}'}\right)} \frac{\vartheta(\mathrm{B})}{\vartheta(\mathrm{A})} \tag{3.9}$$

By using RSFs, it is possible to determine surface densities of other species, if the surface density of the reference species $\vartheta(\mathrm{B})$ is known.

Although the RSFs contain matrix-dependent quantities, their variations are damped to some extent by virtue of taking ratios, and in practice the RSF is assumed constant for low concentrations of A (e.g., < 1 atom %). It can be evaluated from measurements on a well-characterized set of standards containing A in known dilute concentrations. The accuracy of the method, however, is not as high as in Laser-SNMS and XPS.

3.1.1.4. Spectral Information

An SSIMS spectrum, like any other mass spectrum, consists of a series of peaks of varying intensity (i.e., ion current) occurring at certain mass numbers. The masses can be allocated on the basis of atomic or molecular mass-to-charge ratio. In metal and semiconductor surfaces, many of the more prominent secondary ions happen to be singly charged atomic ions, which makes allocation of mass numbers slightly easier. Masses can be identified as arising either from the substrate material itself, from deliberately introduced molecular or other species on the surface, or from contamination and impurities on the surface. Complications in allocation often arise from isotopic effects. Although some elements have only one principal isotope, in many others the natural isotopic abundance can cause difficulties in identification.

Figure 35 shows the positive SSIMS spectrum from a silicon wafer, illustrating both the allocation of peaks and the potential problems with isobars. SSIMS reveals many impurities on the surface, particularly hydrocarbons, for which it is especially sensitive. The spectrum also demonstrates the reduction in isobaric interference through high mass resolution. For reasons discussed in Section 3.1.1.2, the peak heights cannot be taken to be directly proportional to the concentrations on the surface, and standards must be used to quantify trace elements.

Figure 36. Positive SSIMS spectrum of polystyrene (M_{n} = 5100, $M_{\mathrm{n,\,calc.}}$ = 4500, $M_{\mathrm{n,\,corr.}}$ = 5600) from time-of-flight mass spectrometer [194]

The relationship between what is recorded in an SSIMS spectrum and the chemical state of the surface is not as straightforward as in XPS and AES (see Chap. 2). Because of the large number of cluster ions that appear in any SSIMS spectrum from a multicomponent surface (e.g., while studying a surface reaction), a great deal

of chemical information is available in SSIMS, potentially more than in XPS. The problem in using the information from a cluster ion lies in the uncertainty of knowing whether or not the cluster is representative of a group of the same atoms situated next to each other in the surface. For some materials, such as polymers, the clusters observed are definitely characteristic of the material, as seen in Figure 36 from Bletsos et al. [194], in which the TOF-SSIMS spectrum of polystyrene reveals peaks spaced at regular 104 mass unit intervals, corresponding to the polymer repeat unit. In the characterization of additives in plastic materials, SSIMS measurements have also proved to be a very powerful tool. However, in oxidation studies, for example, many metal – oxygen clusters are generally found in both positive and negative secondary-ion spectra, whose relationship to the actual chemical composition is problematic. Figure 37 from McBreen et al. [195] shows the SSIMS spectra recorded after interaction of oxygen with half a monolayer of potassium adsorbed on a silver substrate. Both the positive and the negative spectrum show evidence of K_iO_j clusters which the authors were unable to relate to the surface condition, although quite clearly much chemical information is available. Sometimes, the use of pure and well-characterized standards can be of help in the interpretation of complex spectra.

In conclusion, SSIMS spectra provide not only evidence of all the elements present, but also detailed insight into the molecular composition. Quasimolecular ions can be desorbed intact up to 15 000 amu, depending on the particular molecule [196] and on whether an effective ionization mechanism is present. Larger molecules can be identified from fragment peak patterns which are characteristic of the particular molecules. If the material being analyzed is completely unknown, spectral interpretation can be accomplished by comparing the major peaks in the spectrum with a library of standard spectra.

3.1.1.5. Applications

In general, SSIMS tends not to be used for quantifications of surface composition because of all the uncertainties described above. Its application has been more qualitative in nature, with emphasis on its advantages of high surface specificity, very high sensitivity for certain elements and molecules, multiplicity of chemical information, and high spatial resolution in the TOF imaging mode. It can be applied to determine the surface composition and existing surface contaminants as a function of lateral position for all kinds of materials such as metals, alloys, semiconductors, oxides, carbides, ceramics, glasses, organic molecular species, organometallics, biomolecules, polymers, etc. It can also be applied to study surface phenomena such as adhesion, chemi- and physisorption, wettability, wear and tear, lubrication, chemical reactivity, corrosion, surface diffusion, segregation, etc. As a common analyzing tool, it is used for numerous applications such as coatings, composite materials, micro- and nanoelectronics, heterogeneous catalysis, biosensors, combinatorial chemistry, pharmaceuticals, medical implants, chromatographies, sensors, painting, environment control and protection, failure analysis, etc.

3.1.1.5.1. Oxide Films

Compared to XPS and AES, the higher surface specificity of SSIMS (1 – 2 monolayers versus 2 – 8 monolayers) can be useful in more precisely establishing the chemistry of an outer surface. Although from details of the O 1s spectrum, XPS could give the information that OH and oxide were present on a surface, and from the C 1s spectrum that hydrocarbons and carbides were present, only SSIMS could say which hydroxide and which hydrocarbons. In the growth of oxide films for various purposes (e.g., passivation or anodization), such information is valuable since it provides a guide to the quality of the film and the nature of the growth process.

One important area in which the properties of very thin films play a crucial role is the adhesion of aluminum to aluminum in the aircraft industry. For bonds of the required strength to form, the aluminum surfaces must be pretreated by anodization, which creates not only the appropriate chemical conditions for adhesion, but also the correct structure in the resultant oxide film as well. Films formed by anodizing aluminum in phosphoric acid under ac conditions were studied by Treverton et al. [197] using

a combination of SSIMS and XPS. Knowledge of both the chemistry of the outer monolayers in terms of aluminum oxides and hydroxides, and of the nature and degree of any contamination introduced by the anodizing process, was important. Figure 38 compares the positive and negative SSIMS spectra after anodizing for 3 and 5 s at 20 and 50 Hz. Both sets of spectra show that the longer anodizing treatment caused significant reduction in hydrocarbon contamination (peaks at 39, 41, 43, 45 amu in the positive spectrum, and 25, 41, 45 amu in the negative), and marked increases in oxide- and hydroxide-associated cluster ions at 44, 61, 70, and 87 amu (positive) and 43 and 59 amu (negative), respectively. At higher masses, peaks allocated to $Al_2O_4H^-$, $Al_2O_3^-$, and $Al_3O_5^-$ were also identified. Residual PO_2^- and PO_3^- from the anodizing bath were reduced as a result of the longer anodizing time. The low level of contaminants is important, since the adhesive coating can then wet the surface more effectively, leading to improved adhesion. In addition, the change from AlO^+ (mass 43) to $AlOH^+$ (mass 44) in aluminum chemistry as a result of going from 3- to 5-s anodizing is a significant effect that could not have been established by XPS.

3.1.1.5.2. Interfaces

The protection of steel surfaces by paint depends significantly on the chemistry of the paint – metal interface. The system has many variables, since the metal surface is usually pretreated in a variety of ways, including galvanizing and phosphating. Indeed, there are likely several interfaces of importance, and corrosion protection may be a function of conditions at all of them.

As one of the final steps in car production, visual checks are performed on the quality of the paint layers, and if defects are observed, paint repair is necessary. Figures 39 and 40 describe the analysis of such a defect (crater in a red paint coat) [198]. The upper sequence of Figure 39 depicts a series of optical images of the defect for different fields of view (the right-hand image is about 150 × 150 µm). Paint remnants can be observed in the center of the crater. The second row of Figure 39 shows ion-induced secondary electron images taken from the crater with a highly focused liquid metal ion beam. The images clearly depict the crater topography.

Figure 37. SSIMS spectra following interaction of oxygen with half a monolayer of potassium adsorbed on silver, at 300 K [195]
A) Positive SSIMS spectrum; B) Negative SSIMS spectrum

Figure 40 shows the secondary ion spectra recorded from within the defect and from its surroundings. The spectrum from the defective area clearly shows the presence of a polluting perfluorinated polyether structure (peaks due to C_xFy^+ and the peak at mass 47 amu (CFO^+) are diagnostic of the polyether structure).

The third sequence in Figure 39 shows mass-resolved secondary ion images recorded from the crater. On the far left, the lateral distribution of the uncharacteristic hydrocarbon $C_3H_3^+$ can be seen. The signal is enhanced in the crater

Figure 38. SSIMS spectra from oxide films formed on aluminum after anodization treatment in phosphoric acid for 3 or 5 s [197]

due to an increased sputter yield. Topographical information can be obtained from hydrocarbon images. The next image shows the lateral distribution of the silicone oil which is incorporated into the paint as a smoothing agent. The silicone oil is only detected from the paint itself and not in the crater bottom. Therefore silicone oil can be excluded as the cause of the defect. The last three images show the lateral distributions of several $C_xF_y^+$ fragments and reveal unambiguously that the perfluorinated polyether is found exclusively in the crater.

Figure 39. Video images, ion-induced secondary electron images, and mass-resolved ion images of a defect in car paint; white signal corresponds to high intensity, black to low intensity [198]

Figure 40. Positive TOF-SIMS spectra from the defective area and from a spot remote from the defect [198]

Later it was found that the polluting lubricant droplets originated from the transport belts used in production; they had fallen into the paint bath and prevented adhesion of the paint to the metal. It can be concluded that especially the high sensitivity of SSIMS in detecting submonolayer coverages of organic species makes it an extremely powerful tool for solving such interface problems.

3.1.1.5.3. Polymers

Treatment of polymer surfaces to improve their properties with respect to wetting or water repulsion and to adhesion is a standard procedure. The treatment is designed to change the chemical properties of the outermost groups in the polymer chain without affecting bulk polymer properties. Any study of the effects of treatment therefore requires a technique that is specific mostly to the outer atomic layers, and hence SSIMS is extensively used in this area.

One of the favored forms of surface treatment is plasma etching. Depending on the conditions of the plasma discharge (i.e., nature of discharge gas, gas pressure, rate of gas flow, discharge power and frequency, and substrate polarity), plasma etching can alter the chemical characteristics of a surface over a wide range. A plasma discharge is by nature highly controllable and reproducible. The effects of plasma treatment on the surface of polytetrafluoroethylene (PTFE) were studied by Morra et al. [199] using combined SSIMS and XPS. They found, as evidenced in Figure 41, that not only did the plasma change the surface chemistry, but the surface emission fragments themselves led to a temporary change in the plasma-discharge conditions. The untreated (Fig. 41 A) and 15-min oxygen-plasma-treated (Fig. 41 C) positive-ion spectra are virtually identical, whereas the 0.5-min oxygen-plasma-treated spectrum (Fig. 41 B) is

quite different. The initial breakup of the PTFE surface produced hydrocarbon fragments which reacted with the oxygen to produce water vapor, thus changing the local nature of the discharge gas. The important deduction to be made is that one of the vital parameters in plasma treatment is the length of contact time; in this case, too long a contact time resulted in no surface changes.

Other SSIMS studies of polymer surfaces have included perfluorinated polyether [200], low-density polyethylene [201], poly(ethylene terephthalate) [202], and the oxidation of polyetheretherketone [203].

3.1.1.5.4. Biosensors

Biosensor chip technology is a subject of growing interest for a variety of applications. In particular, DNA-sequencing chips based on the method of sequencing by hybridization are growing in importance. Unknown DNA sequences, which are typically labeled with radioactive or fluorescent markers, are hybridized to known complementary short DNA sequences called oligodeoxynucleotides (ODN) that have been immobilized on a solid surface [204], [206]. This method has become valuable for clinical diagnostics, the sequencing of cDNAs or the partial sequencing of clones, DNA and RNA sequencing, gene polymorphism studies, and identification of expressed genes. Using peptide nucleic acid (PNA) hybridization biosensor chips [205], [206] would even allow the sequencing of unlabeled DNA. PNA is a synthetic DNA analog in which both the phosphate and the deoxyribose of the DNA backbone are replaced by polyamides, resulting in a phosphate-free backbone of PNA. This allows the detection of the presence of DNA by a phosphate signal.

Figure 42 depicts some TOF-SIMS spectra obtained from ODN and PNA immobilized on silanized silicon wafers. The spectra clearly demonstrate that the masses corresponding to PO_2^- and PO_3^- provide the best correlation to the presence of ODN, and they can be used to precisely distinguish between ODN and PNA. The CF_3^- and $C_2O_2F_3^-$ peaks in the PNA spectra are due to trifluoroacetic acid, which was part of the PNA solution. Signals for the deprotonated forms $(Cyt - H)^-$ and $(Thy - H)^-$ of the bases cytosine and thymine, respectively are observed for both immobilized PNA and ODN sequences and can be used to detect the presence of these bases.

Figure 43 shows the thermal stability of immobilized ODN and PNA. The signal for the Thy and Cyt bases obtained with temperature-programmed SIMS starts to decrease at about 150 °C for ODN, and at about 200 °C for PNA. This variance is caused by the differences in binding strength between the bases and the sugar – phosphate backbone or the peptide backbone, respectively.

The data show that SSIMS can be used as a tool for characterizing the various steps in the production of biosensors or even for sequencing.

Figure 42. Negative TOF-SIMS spectra obtained from oligodeoxynucleotides ODN (left) and PNA (right) [205]

In a similar way, SSIMS can be applied to solve a variety of problems in bioanalytical chemistry, e.g., screening of combinatorial libraries, characterizing Langmuir – Blodgett layers, etc.

3.1.1.5.5. Surface Reactions

Because of the inherently destructive nature of ion bombardment, the use of SSIMS alone in the study of the reactions of surfaces with gases and vapors must be viewed with caution, but in combination with other surface techniques it can provide valuable additional information. The parallel techniques are most often XPS, TDS, and LEED, and the complementary information required from SSIMS normally refers to the nature of molecules on surfaces and with which, if any, other atoms they are combined.

A typical SSIMS spectrum of an organic molecule adsorbed on a surface is that of thiophene on ruthenium at 95 K, shown in Figure 44, from the study of Cocco and Tatarchuk [207]. The exposure was only 0.5 Langmuir (i.e., 5×10^{-7} torr s = 37 Pa s), and the principal positive ion peaks are those from ruthenium, consisting of a series of seven isotopic peaks around 102 amu. However, ruthenium – thiophene complex fragments are found at ca. 186 and 160 amu, each showing the same complicated isotopic pattern, indicating that even at 95 K interaction between the metal and the thiophene hadruthenium – thiophene complex fragments are found at ca. 186 and 160 amu, each showing the same complicated isotopic pattern, and this indicates that even at 95 K, interaction between the metal and the thiophene occurred. In addition, peaks for thiophene and protonated thiophene are observed at 84 and 85 amu, respectively, with the implication that no dissociation of the thiophene had taken place. The smaller masses are those of hydrocarbon fragments of different chain lengths.

SSIMS has also been used in the study of the adsorption of propene on ruthenium [208], the decomposition of ammonia on silicon [209], and the decomposition of methanethiol on nickel [210].

3.1.1.5.6. Imaging

SSIMS has been applied in the TOF-SSIMS imaging mode to study very thin layers of or-

Figure 43. TP-SIMS measurements of an ODN (c = 0.1 mM) and PNA (c = 0.1 mM, curve labeled as PNA) TTTTCCCTCTCTC-sequence [205].

Figure 44. Positive SSIMS spectrum from Ru (0001) after exposure to 0.5 L thiophene at 95 K [207]

ganic materials [211–215], polymeric insulating materials [216], and carbon fiber and composite fracture surfaces [217]. In these studies, a spatial resolution of ca. 80 nm in mass-resolved images was achieved.

Figure 45 shows several mass-resolved images of polymer blends of Nylon 6 (Ny6) and Bisphenol A polycarbonate (PC), mixed for 20 and 40 min respectively [218]. Reactive blending of polymers and exchange reactions that may occur during the melt-mixing process have attracted considerable interest among many researchers. Reactive mixing of immiscible polymers can lead to partial compatibilization of the two components with properties advantageous for technological applications. It is evident that the 20-min sample is quite inhomogeneous, with large distinct domains of different composition,

while the 40-min sample shows a more homogeneous distribution. Detailed spectral analysis of the various imaging regions supported the picture that reactive mixing and compatibilization of Ny6 – PC blends occurs via the incorporation of PC in the nylon phase.

TOF-SIMS imaging can also be used to detect extremely small particles on various substrates such as silicon wafers or photographic films [219]. Figure 46 depicts images of silver bromide and silver chloride crystals, demonstrating the high spatial resolution (50 nm) possible with TOF-SIMS. Current development is aiming to reach a spatial resolution for chemical mapping of about 20 nm.

3.1.1.5.7. Ultrashallow Depth Profiling

TOF-SIMS is well established for surface analysis under static conditions. More recently, TOF-SIMS has also proved to be a very powerful tool for ultrashallow depth profiling, having the advantage of simultaneously detecting all elements of interest. Especially the dual-beam mode [220] (see Section 3.1.2.2.1) enables optimal depth resolution, since sputtering conditions can be independently optimized. Figure 47 depicts an ultrashallow TOF-SIMS depth profile of a 100 eV B implant in Si, capped with 17.3 nm of Si. The measurement was performed with 600 eV SF_5^+ sputtering and with O_2 flooding. The original wafer surface into which the B was implanted is indicated by the maxima of the alkali metal and C signals. Due to these contaminants, the ^{30}Si signal exhibits a minimum. The B profile shows a dynamic range of more than 3.5 decades and a depth resolution of ≤ 0.5 nm.

3.1.2. Dynamic SIMS

Dynamic SIMS is a standard technique for the measurement of trace elements in semiconductors, high-performance materials, coatings, and minerals. The main advantages of the method are the excellent detection limit of less than 1 ppm for all elements, the isotopic sensitivity, the inherent possibility of measuring depth profiles, and the capability for fast direct imaging and 3D detection of species distribution.

The first SIMS instrument was built by Herzog and Viehboeck [221] in Vienna in the 1940s. In the early 1960s, Herzog and Liebl [222] built the first sophisticated SIMS instrument, nearly at the same time as Castaing and Slodzian in Paris [223]. In 1970, Benninghoven was the first to use the acronym SIMS [224].

3.1.2.1. Principles

The bombardment of a sample with a dose of high-energy primary ions (1 – 20 keV) results in the destruction of the initial surface and near-surface regions (see Section 3.1.1.1). If the primary ion dose is higher than 10^{11} ions/mm^2 the assumption of an initial, intact surface is no longer true. A sputter equilibrium is reached at a depth greater than the implantation depth of the primary ions. The permanent bombardment of the sample with primary ions leads to the following effects.

Compensation of Preferential Sputtering. The species with the lower sputter yield is enriched at the surface. This effect is called preferential sputtering and complicates, for example, Auger measurements. The enrichment compensates for the different sputter yields of the compound or alloy elements; thus in dynamic SIMS the flux of sputtered atoms has the same composition as the sample.

Atomic Mixing. Depending on their mass, energy, and impact angle the primary ions reach a mean depth until they are finally stopped by many collisions with sample atoms. Also, sample atoms are moved from their initial locations (see Section 3.1.1.1). This results in atomic mixing of the near-surface region and limits the depth resolution. Small primary ion energies and oblique bombardment angles reduce this effect.

Implantation of Primary Ions. The primary ions are implanted in the sample and thereby influence the chemical constitution. For energies on the order of 20 keV, the implantation depth is about 30 nm. The sputter yield, i.e., the ratio of secondary to primary particles (not only ions), is energy dependent and has a maximum around 10 keV.

Figure 45. Secondary ion images of PC – Ny6 blends melt-mixed for 20 min (top) and 40 min (bottom). Images A and B were obtained by adding the mass-resolved images pertaining to the masses listed below each image. Also shown are the overlays of A (black) and B (white) [218].

Figure 46. High-resolution TOF-SIMS images of silver bromide and silver chloride crystals

Crater-Bottom Roughening. Depth resolution is also limited by roughening of the crater bottom under ion bombardment. On polycrystalline samples this can be due to different sputter yields of different crystal orientations, since the sputter yields of single crystals can vary by a factor of two depending on their orientation. Due to this type of roughening, depth resolution deteriorates with increasing depth.

Sputter-Induced Roughness. Sputtering single crystal semiconductors, in particular II-VI semiconductors, with Cs^+ ions results in surface roughening. Until now there is no satisfactory explanation of this effect. This effect and the corresponding reduction of the depth resolution can be avoided by rotating the sample during the measurement.

Charging Effects. The electrostatic potential of nonconducting samples and layers is changed due to the bombardment of charged atoms and the emission of secondary electrons and ions. Usually this results in a positive charging of the sample and a corresponding drift of the secondary ions' energy. On good insulators this

charging reaches such high values that the primary ions are repelled by the surface, and analysis becomes impossible. To compensate for this effect, low-energy electrons can be directed to the surface ("electron shower").

Figure 47. Multi-element depth profile of a B layer in Si performed with 600 eV SF_5^+ sputtering [220]

Secondary Ion Formation. Due to the complex situation on the surface, a satisfactory theoretical description of the ionization process is not yet possible. Different ionization mechanisms have been proposed.

Electron-Tunneling Model. Several models based on a quantum mechanical concept have been introduced. One idea is that one electron of the conducting band tunnels to the leaving atom or vice versa. The tunneling probability depends on the ionization potential of the sputtered element, the velocity of the atom (available time for the tunneling process), and the work function of the metal (adiabatic surface ionization, Schroeer model [225]).

Broken-bond models were especially developed to describe the ionization process of ionic compounds, especially under primary oxygen bombardment or gas admission ("O_2 shower"). The model assumes the building of an oxide layer on the surface. The binding electrons remain at the oxygen atom, and therefore positively ionized atoms are emitted [226].

Local Thermodynamic Equilibrium (LTE). The LTE model has only historical importance. The idea was that under ion bombardment a near-surface plasma is generated in which the sputtered atoms are ionized [227]. The plasma should be under local equilibrium, so that the Eggert – Saha equation for determination of the ionization probability can be used. The important parameter was the plasma temperature; given the concentration of one element, this temperature was determined. The theoretical background of the model is not applicable. The reason why it gives semi-quantitative results is that the exponential term of the Eggert – Saha equation also fits to quantum mechanical expressions.

3.1.2.2. Instrumentation

The basic instrumental setup for dynamic SIMS is the same as for SSIMS (Section 3.1.1). Depending on the required intensity, beam diameter, and ion species, different ion sources are used. Several mass analyzers with different characteristics enable a broad range of applications.

3.1.2.2.1. Ion Sources

Bombardment with reactive species increases the ionization yield and therefore SIMS sensitivity. Electropositive elements are more sensitive under oxygen bombardment, and electronegative elements under cesium bombardment (see Section 3.1.2.3). Therefore in dynamic SIMS usually Cs^+ or O_2^+ ions are used for sample sputtering. Because of the lower melting point of gallium and hence the higher achievable brightness of a Ga^+ source, this type is also used for fine-focus imaging applications, despite its lower sensitivity. The liquid-metal ion source (LMIS) described in Section 3.1.1.1.1 can also be run with Cs^+; O_2^+ beams are produced in electron impact/extraction or duoplasmatron sources.

Duoplasmatron (Figure 48). In the Duoplasmatron, gas-discharge ion sources are used for bombardment with oxygen or argon. In dynamic SIMS, especially the use of O_2^+ ions is common because of the chemical enhancement effect. With a Duoplasmatron, ion beam currents

of several microampere can be generated. The diameter of the beam can be focused down to 0.5 µm. The attainable particle current density of the beam (ions per square micrometer per second)) is an inherent property of the ion source, the so-called brightness. Hence a decrease in the beam diameter is associated with a reduction of the beam current.

Figure 48. Schematic of a Duoplasmatron ion source

Dual-Beam Technique for TOF Instruments. Because of their low duty cycle, TOF instruments are not recommended for common depth profiles. If only one fine-focus pulsed ion gun is used, the sample is bombarded by primary ions for only 0.1 % of the time; therefore, it would take a long time to reach deeper regions. However, by using a second ion gun working anticyclic to the "measuring" beam without an applied accelerating potential, substantial amounts of sample material can be removed. One advantage of this dual-beam technique is that sputtering for measurement and sputtering for material removal are not coupled, and so beam diameter, energy, mass, and angle of the "removal" gun can be optimized independently of the "measuring" gun. A disadvantage is that atoms sputtered during the material-removal phase are not analyzed. This reduces the detection power. Simultaneously detecting all masses can only partially compensate for this disadvantage, especially in implantation profiles where only one mass is of interest.

3.1.2.2.2. Mass Analyzers

Apart from the quadrupole and TOF analyzers described in Section 3.1.1.1.2, the most important types of mass analyzers used in common dynamic SIMS instruments employ a magnetic sector field.

Magnetic Sector Field. In a magnetic field $\boldsymbol{B}$ an ion with velocity $\boldsymbol{v}$ and charge q experiences a centripetal force $\boldsymbol{F}$, known as the Lorentz force:

$$\boldsymbol{F} = q \cdot (\boldsymbol{v} \times \boldsymbol{B}) \tag{3.10}$$

This force must be balanced by the centrifugal force of the ion mv^2/r, where r is the radius of curvature of the trajectory. Hence

$$\frac{mv^2}{r} = q \cdot (\boldsymbol{v} \times \boldsymbol{B}) \tag{3.11}$$

Due to this force, particles with an energy $E = mv^2/2$ are held on circular paths of radius r:

$$r = \sqrt{\frac{2E\,(m/q)}{\boldsymbol{B}}} \tag{3.12}$$

Secondary ions are accelerated from the surface to a certain energy. After passing an entrance slit, different masses are forced to follow different radial paths in the homogeneous magnetic field. Only mass m ($\pm\,\Delta m$), defined by

$$\frac{m}{q} = \frac{\boldsymbol{B}^2 r^2}{2E} \tag{3.13}$$

is able to pass the exit slit and reach the detector. Since the formation probability of singly ionized atoms is considerably higher than that of more highly charged particles, q in Equation (3.4) can normally be set to unity. By scanning the magnetic field, all masses are detected sequentially.

Two types of commercial magnetic sector field instruments will be described in the following:

The *direct-imaging magnetic sector mass analyzer* (Fig. 49) has the unique property that all parts (lenses, ESA, and magnetic sector field) of the secondary ion optic are stigmatic (comparable to light microscopes). This means that all points of the surface are simultaneously projected into the analyzer.

The *Mattauch–Herzog geometry* (Fig. 50) allows the detection of several masses simultaneously and is therefore ideal for scanning instruments [228]. Up to five detectors are adjusted mechanically to locations in the detection plane, that is, to masses of interest. Thus, it is possible to detect, for example, all isotopes of an element simultaneously in a certain mass range. Also fast, sensitive, and precise measurements

of distributions of different isotopes are feasible, and this allows of isotope ratios of small particles visible in the image to be calculated. The only commercial instrument of this type (Cameca Nanosims 50) uses a coaxial optical design of the ion gun and the secondary ion extraction and provide a lateral resolution of 50 nm.

Figure 49. Basic set-up of a direct-imaging magnetic sector instrument. The stigmatic secondary ion optics consists of an electrostatic analyzer (ESA) and a magnetic sector field.

Figure 50. Schematic drawing of a Mattauch – Herzog magnetic sector instrument with simultaneous mass detection

3.1.2.2.3. Detectors

Ion intensities up to a count rate of two million are measured with an electron multiplier. Above this value a Faraday cup is used. Its ion – current amplification must be adjusted to fit the response of the electron multiplier.

For the measurement of local ion intensities in the direct-imaging mode (see Fig. 49), amplification ensuring laterally uniform single-ion detection is necessary. Depending on the sensitivity of the detector, single or double channel plates are used. Two laterally resolving detectors are in use: ccd cameras and resistive anode encoders (RAEs).

For standard *CCD cameras*, a double channel plate (amplification $> 10^6$) is necessary. For high-sensitivity cameras (sensitivity $> 10^{-3}$ lux, cooled or with internal amplification) a single channel plate suffices. By controlling the channel plate voltage (i.e., amplification) one can achieve a high dynamic range with this system [229].

The *resistive anode encoder* (RAE) has the advantage that the single ion events are detected digitally; therefore, it delivers quantitative results, independent of local differences in the amplification of the channel plate. One disadvantage is that the count rate is limited to 200 000.

3.1.2.3. Spectral Information

The element sensitivity is determined by the ionization probability of the sputtered atoms. This probability is influenced by the chemical state of the surface. As mentioned above, Cs^+ or O_2^+ ions are used for sample bombardment in dynamic SIMS, because they increase the ionization probability – the so-called chemical enhancement effect.

The near-surface region is partially oxidized in the case of O_2^+ bombardment. During the sputtering process the chemical bonding of the oxides is broken. The binding electrons have a higher affinity to oxygen; therefore, the (metallic) binding partner leaves the surface positively charged.

Bombardment with Cs^+ results in coverage of the surface with Cs. This reduces the work function and results in a higher probability that an electron from the conducting band tunnels from the surface to the leaving atom during the sputtering process. This effect results in a higher rate of formation of negatively charged atoms, especially of electronegative elements.

Both models have been described theoretically and verified by experiments. Due to the complex surface structures of real samples, there is no quantification algorithm based on physical models yet.

3.1.2.4. Quantification

Since the ionization probability is strongly dependent on the matrix, it is necessary to use standards.

Relative Sensitivity Factor. The most accurate and therefore most popular quantitative method to reduce these influences is to analyze the unknown sample together with a similar sample of known content. Generally, the relationship between measured intensity and content of each sample is defined via the *relative sensitivity factor* (RSF):

$$\frac{I_{\mathrm{el}}}{I_{\mathrm{ref}}} = \mathrm{RSF} \cdot \frac{c_{\mathrm{el}}}{c_{\mathrm{ref}}} \tag{3.14}$$

where ref specifies a matrix element, and el indicates the analyzed element. By using a standard sample with known concentration, the RSF can be made adjustable. By using standards relative precision up to 1 % is possible.

Implantion Standards. The production of homogeneous solid-state standards is costly. Dynamic SIMS has the advantage that nonhomogeneous *ion-implantation standards* can also be used. Given the implantation dose, the RSF can be calculated by summing the signal during a depth profile. Therefore, calculations must be performed with the mean intensity ratio indicated by the sum in Equation (3.15) to obtain the respective RSF.

$$\mathrm{RSF} = \frac{f_{\mathrm{ref}} c_{\mathrm{ref}} \varrho N_{\mathrm{A}} d}{f_{\mathrm{el}} Q_{\mathrm{T}} M C} \cdot \sum_{i=1}^{C} \frac{I_{\mathrm{el}}(i)}{I_{\mathrm{ref}}(i)} \tag{3.15}$$

where f_{ref} is the isotope abundance of the reference, c_{ref} the concentration of the reference in atoms/atom, ϱ the matrix density in g/cm^3, N_{A} the Avogadro number (6.022×10^{23} mol^{-1}), d the depth of the crater in cm, f_{el} the isotope abundance of the element, Q_{T} the implanted dose of the element in atoms/cm^2, M the molecular mass of the matrix, C the number of measured cycles, $I_{\mathrm{el}}(i)$ the signal intensity of the element in counts/s of cycle i, and $I_{\mathrm{ref}}(i)$ the signal intensity of the reference in counts/s of cycle i.

For quantification of multilayers, each layer must be calculated separately. Especially for oxide layers, quantification is not possible due to the variation in the ionization probability in the different layers. Modern materials have a complex three-dimensional inner structure with many different phases. For these samples quantification is not possible, but technologists are often only interested in relative differences between several samples, or they already know the bulk concentrations and are only interested in the elemental distribution.

MCs$^+$ Ions. With Cs bombardment, the matrix effect can be significantly reduced by using the *MCs$^+$ ion signals* for quantification. The detection limit is reduced by two or more orders of magnitude, and in some cases even standard-free quantification is reported [230]. One disadvantage is the high masses of the MCs$^+$ ions, because many mass interferences occur in this mass range.

3.1.2.5. Mass Spectra

Magnetic sector field instruments have mass resolutions up to $m/\Delta m = 20\,000$, quadrupole instruments are limited to a mass resolution of approximately $m/\Delta m = 500$. Both types of instruments provide a mass range up to 500. High mass resolution is needed to separate mass interferences of molecular and atomic ions. Due to the mass defect of the binding energy of the nucleus, atomic ions have a slightly smaller mass than corresponding molecular ions. Typically, mass resolutions between 5000 and 10 000 are necessary.

There is a second method to avoid mass interferences. Molecular ions have a steeper energy distribution than atomic ions, that is, lower abundance at higher energies. By energy filtering, that is gating of low-energy ions, the molecular ions are suppressed. This method also results in a reduction of the detection limit. Figure 51 shows that energy filtering hardly reduces the signal intensities of the atomic ions but strongly suppresses molecular ions. The ^{63}Cu signal is not visible without offset because there are many interferences, e.g., ^{51}V^{12}C.

3.1.2.6. Depth Profiles

The measurement of depth profiles is based on the detection of the masses of interest during sputter removal of the sample material. The evaluation of such an experiment has the following limitations:

– The depth resolution is limited by atomic mixing, roughness of the initial sample surface, and roughening processes during sputtering.

Figure 51. SIMS spectra of a high-speed steel. A) Primary ions: O_2^+, no secondary ion energy limitation, electropositive elements are sensitive, many molecule ions are visible. B) Same parameters, but 300 V offset was used; the molecular ion intensities are reduced significantly. C) Primary ions: Cs^+, 300 V offset was used; therefore, electronegative elements are more sensitive.

– The determination of the depth scale by the measurement of the crater depth may be hampered by the fact that multilayer systems consist of layers with different sputter yields.
– Furthermore, the different chemical constitution of the layers may cause different RSFs for a given element in different layers. These effects may make the determination of the depth scale and the RSF for each layer necessary.

SIMS depth profiles have no significant background; only the elements H, C, and O have a background due to residual gas. This background is only dependent on the gas pressure in the sample chamber, and not on the primary-ion beam intensity. To test the influence of the signal background due to the residual gas, the ion beam current can be reduced for several cycles. All signals should be reduced in the same way; if one signal is not reduced this indicates that it is caused by residual gas.

To illustrate the use of the isotope sensitivity of SIMS, Figure 52 shows a depth profile of a passivation layer on high-purity chromium. The layer was produced by a two-step process: first the sample was oxidized for 30 min in air with natural isotope concentrations. In the second step, the gas was changed to a mixture of ^{18}O and ^{15}N. The profile shows that the ^{18}O layer is located on the top; this indicates that the chromium diffuses to the surface and reacts there with the oxygen. The high dynamic range of SIMS forces the use of logarithmic scales over 6 or 7 orders of magnitude. This has to be kept in mind when interpreting depth profiles; for example, diffusion profiles appear as straight lines. The diffusion of oxygen through the layer to the interface with the metallic chromium is slower by a factor of 50. The enrichment of carbon at the interfaces is due to gas change.

3.1.2.7. Imaging

Scanning SIMS. In the scanning (or microprobe) mode the image is measured sequentially point-by-point. The lateral resolution of the element mapping in scanning SIMS is only dependent on the primary beam diameter. Therefore, mostly LMISs are used. Beam diameters down to 50 nm with high total intensities of 1 nA can be achieved. The beam diameter of oxygen is limited to 0.5 µm by the used Duoplasmatron; for mapping electropositive elements, this necessary because of the chemical enhancement effect.

The counting time per pixel and the number of pixels determine the measurement time of an image. In the case of low concentration of the elements of interest the Poisson statistics of the small integer values of the secondary ions determine the counting time.

A reduction in the measurement time of element distributions is made possible by the simultaneous detection of several masses. This can be achieved only by the use of a magnetic sector field spectrometer with Mattauch – Herzog geometry [228] (Fig. 50) and parallel detection of up to five masses by mechanically adjusted electron multipliers.

Figure 52. Depth profile of a passivation layer on high-purity chromium. The ^{18}O layer is on the top, the ^{16}O layer at the interface with the metal.

Direct-Imaging Mode. In the direct-imaging (or microscope) mode (see Figs. 53 and 54) all pixels of the element distribution are detected simultaneously by using stigmatic secondary ion optics. The lateral resolution of the image is not influenced by the diameter of the primary ion beam. The resolution is determined by the energy distribution of the secondary ions. The energy and angle distributions result in a chromatic aberration of the first electrostatic lens, the emission lens [185]. The resolution can only be increased by limiting the energy (or angle) acceptance of the instrument; this, of course, reduces the transmission and therefore the detection limit. In practice this effect limits the lateral resolution to about 1 µm; only for main components is 0.5 µm possible.

Figure 53. Scanning SIMS image of the carbide structure of a high-speed steel [231]. In the V distribution different phases (MC and M_2C) are visible. The Al distribution shows the shell structure of the NMI (non-metallic impurities) acting as condensation nucleus. Measurement time: 10 min, Image size: 64 x 64 µm. Primary ions: O_2^+, Primary energy: 5.5 keV.

In practice the quality of the image is also reduced by the use of high mass resolution and energy offset, and in many cases it is therefore not possible to avoid mass interferences. By the use of image processing tools for classification of mappings of different masses, determination of element distributions is possible [232].

For secondary-ion detection a laterally resolving detector is necessary. In the first step a channel plate for amplification is used, and the secondary electrons of the output of this device are accelerated either to a fluorescent screen or to a resistive anode. In the case of a fluorescent screen, the image is picked up by a CCD camera and summed frame by frame by a computer. This system has the advantage of unlimited secondary-ion intensities, but compared to the digital detection of the resistive anode decoder, the lateral and intensity linearity is not so well defined.

The advantage of the imaging mode is fast data acquisition. Because all pixels are projected and detected simultaneously, the measurement time of one distribution is extremely low.

Figure 54. Direct-imaging mode SIMS image of a passivation layer on a niobium alloy [233]. The boron enrichment at the interface is not visible by EPMA. Measurement time: 10 s, image diameter: 150 µm, primary ions: O_2^+, primary energy: 5.5 keV.

3D-SIMS (Fig. 55) is a further development combining depth analysis and imaging analysis. In the imaging mode the summing time of single ion distributions is low (1 – 5 s). This enables the possibility of cyclic image acquisition during a normal depth profile. Measurements of large and therefore representative volumes (150 × 150 × 10 µm) in a short time (1 h) are possible [234]. In the scanning mode, the sequential detection of the single pixels and voxels results in long measuring times, and in practice only small volumes (10 × 10 × 1 µm) can be measured [235].

3.1.2.8. Applications

3.1.2.8.1. Implantation Profiles

Ion implantation is a common method for doping semiconductors. Since the concentrations of the dopants (mostly B and P) are very low, a dynamic range of more than five orders of magnitude is often necessary. The measurement of P is more difficult than that of B due to the mass interference of the ^{30}SiH and the ^{31}P ions. A high mass resolution of $m/\Delta m = 5000$ or an energy offset of 300 V is necessary.

To obtain high implant concentrations at large depths and with low damage, channeling is used.

Figure 55. 3D-SIMS measurement of the V distribution in high-speed steel. Dimensions: 150 × 150 × 10 µm, primary ions: oxygen, primary energy: 5.5 keV, primary intensity: 2 µA. A) Block view; B) Isosurface view.

In this case the wafer is bombarded in a high-index crystal direction so that the implant ions can penetrate the solid mostly along the "channels" between the occupied lattice positions. However, the formation of a small number of defects restricts the use of the channeling effect to the upper limit of implantation concentrations.

The depth profiles in Figure 56 show that the typical flat channeling implantation profile is generated with low doses only. Increasing the dose superimposes the normal implantation profile. Undertaking such experiments with homogenous wafers allows the calibration of models for semiconductor production.

3.1.2.8.2. Layer Analysis

The benefits provided by surface-coating techniques have the common goal to increase productivity and reduce costs [236]. CrN provides excellent material properties to meet these requirements. It has high hardness, superior oxidation stability, high corrosion resistance, low friction coefficient, and good adhesion. Because of its outstanding properties CrN is often applied in the machining of iron-based materials and wear parts. Although CrN already has extraordinary material properties, further improvement is essential. For this reason it is very important to have not only exact but also complete information about the presence of desired or undesired trace elements within these layers. Figure 57 shows the depth profile of such a layer; an enrichment of Ti and Al at the interface to the substrate is visible. The Si signal in the layer increases with depth. It is not possible to determine from the depth profile alone whether diffusion of Si into the CrN layer occurs (see below).

Figure 58 shows 3D-SIMS distributions of the elements Si, Al, Ti, and Cr. The Cr distribution is shown from the bottom side to illustrate the rough interface. It is evident that the interfaces are not smooth. This is the reason for the slowly decreasing Cr signal. As can be seen in the 3D distribution the different depth profiles of Si, Ti, and Al in the layer are due to respective particulate inclusions.

From the depth profile alone it is not distinguishable whether the profile shape is a result of diffusion of elements or due to geometric effects. This example demonstrates the ability of 3D-SIMS to improve the information content of depth profiles.

Figure 56. Depth profiles of P implantations in Si. Primary ions: Cs^+, primary energy: 14.5 keV.

Figure 57. Depth profile of a CrN layer deposited on Si. Primary ions: O_2^+, primary energy: 5.5 keV, primary intensity 2 µA, measuring time: 1 h.

3.1.2.8.3. 3D Bulk Element Distribution

Steel alloyed with ca. 1 % Al shows a higher resistance to oxidation at high temperatures. Powder metallurgical, hot isostatically pressed steels have a better macro- and microscopic homogeneity of the distribution of all elements. Combining these advantages should result in higher performance of high-speed steels.

The steel particles are covered with an Al_2O_3 layer before hot isostatic pressing [237]. 3D SIMS measurements (Fig. 59) shows that this layer still exists in the compacted material. Carbonitrides are precipitated as small particles with a diameter of 30 nm inside the particles. As an example for a trace element with concentration in the ppm range, the distribution of Ca^+ ions is shown.

3.2. Secondary Neutral Mass Spectrometry (SNMS)

3.2.1. General Principles

The limitations of SIMS – some inherent in secondary ion formation, some due to the physics of ion beams, and some due to the nature of sputtering – have been mentioned in Section 3.1. Sputtering produces predominantly neutral atoms; for most of the elements in the periodic table the typical secondary ion yield is between 10^{-2} to 10^{-5}. This leads to a serious sensitivity limitation when extremely small volumes must be probed, or when high lateral and depth resolution analyses are needed. Another problem stems from the fact that the secondary ion yield can vary by many orders of magnitude as a function of surface contamination and matrix composition making quantification very difficult. Quantification can also be jeopardized by interferences from molecules, molecular fragments, and isotopes of other elements having the same mass as the analyte. Very high mass resolution can reject such interferences but only at the expense of detection sensitivity.

To improve sensitivity and quantification, several post-ionization methods have been developed. These techniques decouple the sputtering and ionization processes by ionizing the *sputtered neutrals* (SNs) after emission from the sample surface. While the *secondary ion* (SI) yield can vary widely with the surface composition, this is not true of the SN yield. For example, a variation in the SI yield over three orders of magnitude (10^{-2} to 10^{-5}) produces less than a 1 % change in the SN yield. As a result, SNMS has much smaller matrix effects than SIMS. Still, changes in sputter yield (as a function of matrix) can cause quantification errors. These can be corrected by using standards or by determining the various sputter yields. Recombination ef-

Figure 58. 3D depth profile of the CrN layer on Si substrate; same measurement as Figure 40. The CrN layer thickness is 2.3 µm, diameter 150 µm. The Cr distribution is shown from the bottom side.

fects and incomplete atomization are other possible sources of matrix effects in SNMS.

Compared to the other methods of surface and thin film analysis, the main advantages of SNMS are:

- Compared to XPS and AES sputter depth profiling: After attaining sputter equilibrium, and until a layer with different sputtering behavior is reached [238], the SN flux represents stoichiometry and not the altered layer concentrations evolving due to preferential sputtering effects.
- Compared to GD-OES (and -MS, if used for depth profiling): SNMS provides better depth resolution (1 nm instead of 10 nm range) and hardly any formation of molecules with the plasma gas (Ar), unlike the GD techniques, where argides are formed due to the comparatively high pressure.

Figure 59. 3D element distribution of powder metallurgically produced steel. Edge of the cube: 150 µm. Primary ions: 0.1 µA Cs^+ (top), 2 µA O_2^+ (bottom), depth: 1 µm, (top), 11 µm (bottom).

Depending on the matrix and the post-ionization technique, SN^+ spectra can be dominated by atomic or by molecular signals. Compounds with high mass differences between the constituent elements and strong chemical bonds, e.g., result in significant amounts (10 – 100 % of the metal monomer) of molecules, mostly dimers, even if post-ionized by electrons. Then, isobaric interferences from molecular signals have to be considered.

Figure 60. Schematic of an electron-beam SNMS setup (after [240])

SNMS sensitivity depends on the efficiency of the ionization process. SNs are post-ionized by electrons from a broad electron beam or a high-frequency (HF) plasma (i.e., an electron gas), or, most efficiently, by photons from a laser. Particularly the photoionization process allows the fragmentation rate of sputtered molecules to be adjusted by varying the laser intensity, pulse width, and/or wavelength.

SNMS is suitable for quantitative element depth profiles of metallic and electrically insulating samples. Laser SNMS enables the additional acquisition of 2D element distributions; with HF-plasma SNMS bulk analysis is also feasible.

3.2.2. Electron-Beam and HF-Plasma SNMS

3.2.2.1. Principles

The basic principle of electron-beam SNMS, as introduced by Lipinsky et al. in 1985 [239], is simple (Fig. 60): As in SIMS, the sample is sputtered with a focused ion beam. SN post-ionization is accomplished with an electron beam accelerated between a filament and an anode. The applied electron energy ($E_e \approx 50 \pm 20$ eV) is higher than the range of first ionization potentials (IP) of the elements (4 – 24 eV; see Fig. 61). Typical ionization probabilities are in the 0.01 % range. SI^+ and residual gas suppression is achieved with electrostatic lenses prior to SN post-ionization and energy filtering, respectively.

Figure 61. Distributions $f(E_e)dE_e$ of electron energy (E_e) for a low-pressure HF-plasma (suffix pl, Maxwellian, with temperature $T_e = 80\,000$ K) and an electron beam (suffix eb, simplified to Gaussian shape with 40-eV half-width); $\sigma_X(E_e)$ of the E_e-dependent electron-impact ionization cross section for X = Ti calculated according to LOTZ [241]; $f^+_X(E_e)dE_e$ (X = Ti) of the differential ionization rate constant (see Section 3.2.2.4); and respective calculated post-ionization probabilities α^0_X for X = Na, Ti, Si, O, and He, in the order of their first ionization potentials IP, for the HF-plasma parameters given in Section 3.2.2.4

OECHSNER's basic diagram of HF-plasma (or electron-gas) SNMS (Fig. 62) [242] was first published in 1966 [243]. An inductively coupled, low-pressure, HF noble gas plasma (mostly used: Ar, density $n_{pl} \approx 10^{10}\,cm^{-3}$) serves for sputtering by means of the ion component, and for postionization by the Maxwellian electron gas. Its temperature $T_e \approx 10^4 - 10^5$ K fits the given IP range well; depending mostly on IP and on the plasma (i.e., electron) density n_e, ionization probabilities are mostly in the 0.1 % range. Conducting samples introduced into the plasma are set to a negative potential U_{DBM} (DBM: direct bombardment mode) of a few hundred volts. Accelerated by the difference between U_{DBM} and plasma potential (ca. $+30 \pm 5$ V), Ar^+ ions are able to induce comparatively shallow subsurface collision cascades with sputter yields Y on the order of 0.1 – 1.

Positive secondary ions (SI^+) are repelled by an electrode in electron-beam SNMS or completely (in DBM) or widely (in HFM; see below) re-attracted by the sample surface in HF-plasma SNMS. Ionized contaminating species are suppressed by energy filtering.

3.2.2.2. Instrumentation

The electron-beam SNMS setup is shown schematically in Figure 60. The SN flux through the ionization region, which is a few centimeters in length, is crossed by an electron current in the lower milliampere range. Instead of the simple lens depicted in Figure 60, an electrostatic analyzer can serve for energy discrimination of SN^+ against ionized residual gas (1 – 10 eV vs. 10 meV). In contrast to the other SNMS techniques, electron-beam SNMS modules can easily be an added onto many existing UHV-based surface analysis instruments. Compared to a plasma, the lack of positive-charge carriers in an electron beam gives rise to space charge limitations.

A scheme of the commercially available INA-3 type spectrometer (SPECS, Berlin, Germany) is given in Figure 63. A constant Ar pressure of 0.3 ± 0.1 Pa is maintained by a piezo-valve between the high-pressure supply and the cylindrical plasma chamber (volume: 1.26 L; typically used values are given). The HF power of 150 ± 30 W is supplied from an HF generator by a single-turn coil. Electron cyclotron wave resonance [244] is effected, and skin effects of the electron gas are suppressed by a static magnetic field in the millitesla range, maintained by a constant current of 5 ± 2 A flowing through two parallel, rectangular Helmholtz coils with 184 turns each, 25 cm apart. Delivering primary ion current densities of 0.1 – 1 mA/cm^2, the plasma can effect sputter rates in the range of 0.1 – 1 nm/s. If U_{DBM} is fitted appropriately to n_e and T_e with a given distance between sample surface and

Figure 62. Basic principles of HF-plasma SNMS.
ν_{HF}, P_{HF}: HF generator frequency and power, respectively; p_{Ar}: plasma gas (Ar) pressure; T_e, T_{Ar}: electron and plasma gas temperatures, respectively; $n_{pl} = n_e$: plasma (e^-, Ar^+) density; B_0: magnetic flux; U_{DBM}, U_{HFM}: DC or HFM bombardment voltage, respectively (see text); U_s: surface potential vs. ground (HFM); $U_{pl,w}$: plasma sheath edge potential; $SN^{(+)}$: (post-ionized) secondary neutrals; SI^+: positive secondary ions.

plasma sheath edge, sputter erosion occurs with perfect lateral homogeneity, that is, nanometer depth resolution, on a spot 2 – 5 mm in diameter [245]. This compares to removing sand grains from a soccer field layer by layer; rough surfaces, of course, yield less ideal depth resolutions. The large area sputtered with high current density is one of the reasons why typical signal intensities are an order of magnitude higher than in electron-beam SNMS.

The gas temperature of the Ar plasma in the range of 600 ± 100 K results in temperatures of water- and liquid-nitrogen-cooled samples of 350 ± 30 and 200 ± 30 K, respectively. In addition, C, N, and O species desorbed from the chamber walls cause a plasma contamination level in the range 0.01 – 0.1 %.

After post-ionization in the cylindrical plasma space, 3 cm long, between the sample surface and the opposite wall, the SN^+ enter a 90° electrostatic ion energy analyzer (ion optics) that suppresses ionized plasma gas particles by a factor of $10^8 - 10^9$; noise levels are correspondingly low (1 Hz). Optical transmission is on the order of a few per cent.

In both electron post-ionization techniques, mass analysis is performed by a quadrupole mass analyzer (see Section 3.1.1.1.2), and pulse counting by a dynode multiplier. In contrast to a magnetic sector field, a quadrupole mass analyzer enables swift switches between mass settings, thus enabling continuous data acquisition for many elements even at high sputter rates within thin layers.

With useful yields typically around 10^{-10} – a value that also holds for electron-beam SNMS – typical measured intensities are in the range $10^4 - 10^6$ for HF-plasma SNMS, depending on the material and U_{DBM}. A typical plasma and a low U_{DBM} of around 300 V gives ultimate depth resolution and low intensities, whereas a U_{DBM} of 800 V enables bulk analysis in the parts-per-million range (apart from C, N, and O that are implanted from contamination) but poor depth resolution.

Electrically insulating materials can be analyzed in HF-plasma SNMS by applying a square-wave HF in the range of 100 kHz to the sample (Fig. 64). Dielectric charge transfer at the start of a period shifts the surface potential to the applied amplitude U_{HFM}. Ar^+ ions are attracted from the plasma and sputter the surface until the end of Δt^-. Then the potential increase $\Delta U_s = 10 - 100$ V caused by their charge is converted to a positive absolute ΔU_s, which is diminished to less than 1 V within < 0.1 µs by

Figure 63. Schematic of the commercial INA-3 HF-plasma SNMS apparatus (SPECS, Berlin, Germany)

the plasma electron current. The missing sputtering time of Δt^+ and, more important, the often low sputter yield of dielectrics, especially oxides, give rise to lower intensities than given above.

A novel HF-plasma SNMS instrument which can be combined with XPS has been developed [246]. Detection limits in the parts-per-billion range have been attained on a dedicated HF-plasma instrument attached to a double-focusing mass spectrometer [247].

3.2.2.3. Spectral Information

Spectral information in electron-beam and HF-plasma SNMS, both being dynamic sputtering methods, is similar to dynamic SIMS. Since molecules from a heavily sputtered surface survive a collision cascade and an electron impact to a comparatively low extent, emphasis lies on elemental analysis based on mostly atomic spectra. Binary molecules formed from main constituents may add restricted speciation information. Multiple SN ionization occurs rarely because of the low probability of a second electron impact. As a consequence, electron-beam and HF-plasma SNMS spectra show a low degree of interference and are easy to interpret. Figure 65 shows a typical HF-plasma SN^+ mass spectrum, obtained from a Ti – Al alloy. The quadrupole mass detctor is the reason for Δm being unity throughout the spectrum. As discussed above, molecular intensities are in the per cent range of the parent peaks, doubly ionized species appear in the per mil range, i.e., for main constituents only, and adsorbed or implanted plasma gas contamination gives rise to a few additional low-intensity peaks.

Figure 64. HFM principle
––– Applied voltage; —— Variation of surface potential U_s with time t

3.2.2.4. Quantification

The measured SN^+ intensity $I_X(E_{X,0})$ of element X, its SN being sputter emitted with energy E_0, is given by

$$I_x\left(E_{X,0}\right) = \frac{I_{G+}}{e_0}\Delta Y_x\left(E_{X,0}\right) W_X n_e t_X\left(E_{X,0}\right) F_X^+ T_{X+} \qquad (3.16)$$

where I_{G+}/e_0 is the primary ion particle current (e_0 = elementary charge); $\Delta Y_X(E_{X,0})$ the sputter yield of X valid for the emission energy range

Figure 65. HF-plasma SNMS survey spectrum of a powder metallurgically produced Ti – Al alloy sample. In parentheses: signals coming from adsorbed and re-sputtered plasma gas contamination. Sample: Ti-48Al-2Cr-2Nb (mol-%)

Figure 66. Experimental, Fe-related HF-plasma SNMS sensitivity factors $S_{(\mathrm{Fe})\mathrm{X}}$ with elements X ordered according to their post-ionization probabilities α_{X}^{0} calculated according to [253]; from [250] (salts); [251] (alloys); [252] (round robins, r.r.).

$E_{\mathrm{X},0} \pm \Delta E_{\mathrm{f}}/2$, ($\Delta E_{\mathrm{f}}$ = width of the energy window of the ion optics); W_{X} the probability for an SN emission into the ionization volume (electron beam, plasma) within the acceptance angle of the detection system (10^{-3} range); n_{e} the electron density; $t_{\mathrm{X}}(E_{\mathrm{X},0})$ the dwell time of an X particle with $E_{\mathrm{X},0}$ in the ionization region; T_{X^+} the combined spectrometer transmission and detector response probability for X^+ ions; and F_{X}^{+} is the ionization rate constant [248] (see also Fig. 61):

$$F_{\mathrm{X}}^{+} = \int_{E_{\mathrm{I,X}}}^{\infty} \sigma_{\mathrm{X}}(E_{\mathrm{e}}) \sqrt{\frac{2E_{\mathrm{e}}}{m_{\mathrm{e}}}} f(E_{\mathrm{e}})\,\mathrm{d}E_{\mathrm{e}} = \int_{E_{\mathrm{I,X}}}^{\infty} f_{\mathrm{X}}^{+}(E_{\mathrm{e}})\,\mathrm{d}E_{\mathrm{e}} \tag{3.17}$$

where $E_{\mathrm{I,X}} = \mathrm{IP}_{\mathrm{X}}$ is the ionization potential of X, σ_{X} the total ionization cross-section, $f(E_{\mathrm{e}})$ the distribution of the electron energy E_{e}, and m_{e} the mass of the electron at rest.

The product $n_e t_X(E_{X,0})F_X^+$ is equal to the post-ionization probability α_X^0:

$$\alpha_X^0 = n_e t_X\left(E_{X,0}\right) F_X^+ \tag{3.18}$$

The values $\alpha_{X,pl}^0$ in Figure 61 were calculated with $n_{pl} = n_e = 6 \times 10^{15}\,cm^3$, $E_{X,0} = 30\,eV$ (optics setting), and $l_{pl} = 3\,cm$ long path through the plasma. With a mean electron density $n_{eb} = 8 \times 10^{14}\,m^{-3}$, $E_{X,0} = 10\,eV$, and $l_{eb} = 3\,mm$, the corresponding $\alpha_{X,eb}^0$ amount to 6, 9, 13, 45, and 180 % of the given $\alpha_{X,pl}^0$ values (X = Na, Ti, Si, O, He).

The absolute detection (or sensitivity) factor is

$$S_X = W_X \alpha_X^0 T_{X+} \tag{3.19}$$

and can be related to a reference value S_{ref} according to

$$S_{(ref)X} \equiv \frac{S_X}{S_{ref}} = \frac{I_X}{I_{ref}} \frac{c_{ref}}{c_X} \tag{3.20}$$

since for a multicomponent material emitting only atomic SN after attaining sputter equilibrium, the total sputter yield Y is

$$Y_X = c_X Y \tag{3.21a}$$

$$Y = \sum_{i=1}^{n} Y_i = \frac{e_0}{I_{G^+}} \sum_{i=1}^{n} \frac{I_i}{S_i} \tag{3.21b}$$

$i = 1, 2, ..., X$; n = sample elements.

The differences in post-ionization probability α_M^0 of M = Ti and Al on the one hand, and of Cr and Nb on the other hand, both pairs being present in the same concentrations, are the major reason that the respective signals in Figure 65 are similar but not equal. Figure 66 [249] shows that experimental relative detection factors vary roughly with theoretical α_X^0. This variation by three orders of magnitude is mostly due to F, O, N, C, and Zn (as yet unexplained), with more than one order of magnitude, as well as some alkali and alkaline earth metals with another half order of magnitude. The $S_{(Fe)X}$ of all other elements represented in Figure 66 vary between 0.3 and 3, irrespective of matrix and measurement conditions; depending on the latter, identical $S_{(Fe)X}$ vary by factors of 2 5. It is this narrow range of $S_{(ref)X}$ variation compared to SIMS which has made SNMS famous for its ease of quantification.

Figure 67. HF-plasma SNMS sputter time profile (DBM) of a multilayer system consisting of 10 double layers, 5 nm Cr + 5 nm Ni each, on a Si wafer.

3.2.2.5. Element Depth Profiling

Figure 67 gives an example for the depth resolution routinely achieved with both electron-beam and HF-plasma SNMS on suitable samples. If Equation (3.21) is applicable, that is, all sputtered material was recorded with ΣI_i, then Ye_0/I_{Ar^+} is equal to $\Sigma I_i/D_i$ [254], and depths z can be calculated according to:

$$z = \frac{I_{G^+} tY}{e_0 A_s n_u} \tag{3.22a}$$

$$n_u = \frac{\varrho_s N_A N_u}{M_u} \tag{3.22b}$$

where t is the sputter time, A_s the sputtered sample area, n_u the number density of formula units u (e.g., Ta_2O_5, $Ti_{0.48}O_{0.5}Cr_{0.02}$, ...), ϱ_s the sample density, N_A the Avogadro number, N_u the number of atoms per formula unit, and M_u the relative mass (in Daltons) of u.

Absolute detection factors D_X must be determined for this procedure by integrating intensities over time while sputtering suitable pure element samples and determining the crater volume; in the case of HF-plasma SNMS, the weight loss can also be measured.

Figure 68 shows that good depth resolution can also be maintained on sputtering through an insulating micrometer-thick layer.

3.2.2.6. Applications

Figure 69 exemplifies the use of HF-plasma SNMS in materials research [255]. The intermetallic compound γ-TiAl to which 2 mol % Cr

Figure 68. HF-plasma SNMS sputter time profile (HFM) of a multilayer system consisting of five double layers, 100 nm SiO_2 + 100 nm Si_3N_4 each, on a glass substrate (courtesy of V.-D. Hodoroaba, BAM Berlin, and Schott Glas, Mainz, Germany)

was added to increase the ductility was heated to 1070 K for less than 4 s only and cooled down (A) and or kept at this high temperature for 8 h. In the first case, an oxide layer about 150 nm thick formed with Al_2O_3 enriched at the top. Figure 69 B shows that after this initial oxide layer formation, nitrogen starts to penetrate to the interface between oxide and alloy and oxidizes the latter by forming nitrides. The N enrichment at the interface and tracer experiments [255] furthermore suggest that nitride has continuously been converted to oxide between the oxide layer and the nitride-enriched interface layer. Figure 69 B also shows that Ti diffused outward to form an upper TiO_2-rich layer.

Applications of electron-beam and HF-plasma SNMS have been reported in the following areas:

- Aerosol particles [256]
- X-ray mirrors [257], [258]
- Ceramics and hard coatings [259–263]
- Glasses [264]
- Interface reactions [265]
- Ion implantations [266]
- MBE layers [267]
- Multilayer systems [268]
- Ohmic contacts [269]
- Organic additives [270]
- Perovskite-type and superconducting layers [271]
- Steel [272], [273]
- Surface deposition [274]
- Sub-surface diffusion [275]
- Sensors [276–278]
- Soil [279]
- Thermal barrier coatings [280]

3.2.3. Laser-SNMS

3.2.3.1. Principles

3.2.3.1.1. Nonresonant Laser-SNMS

Surface analysis by nonresonant (NR) Laser-SNMS [281–285] has been used to improve the

ionization efficiency while retaining the advantages of probing the neutral component. In NR-Laser-SNMS, an intense laser beam is used to nonselectively ionize all elements and molecules within the volume intersected by the laser beam (see Fig. 70). With sufficient laser power densities, it is possible to saturate the ionization process. For NR-Laser-SNMS, adequate power densities are typically achieved only in a small volume at the focus of the laser beam. This limits sensitivity and leads to problems with quantification due to the differences in effective ionization volume for different elements. The nonresonant post ionization technique provides rapid, multielement and molecular survey measurements with significantly improved ionization efficiency over SIMS, but it still suffers from isobaric interferences.

3.2.3.1.2. Resonant Laser-SNMS

Resonant (R) Laser-SNMS [286–291] has almost all the advantages of SIMS, electron-SNMS, and NR-Laser-SNMS, but it has the additional advantage of using a resonance laser ionization process which selectively and efficiently ionizes the desired elemental species over a relatively large volume (see Fig. 70). For over 80 % of the elements, R-Laser-SNMS has an ionization efficiency of alnost unity over a large volume, so the overall efficiency is greater than that of NR-Laser-SNMS. Quantification is also made simpler because the unsaturated volume (where ionization is incomplete) is insignificant compared to the saturated volume. This leads to consistently high sensitivity and great accuracy in the R-Laser-SNMS measurements. Particularly the extremely high selectivity prevents almost all isobaric and molecular interferences. This improves the accuracy of the data and simplifies its interpretation without requiring very high resolution mass spectrometry. The main drawbacks accompanying this immunity to interference are that only one element is analyzed at a time and that low-repetition-rate pulsed lasers impose a low duty cycle. The use of multiple lasers permits the simultaneous ionization of multiple elements, but this is practically limited to two to three elements. Advances in diode-pumped Nd:YAG lasers and optical parametric oscillators (OPOs) will allow increased repetition rates of over 1 kHz as opposed to 30 – 100 Hz.

3.2.3.1.3. Experimental Setup

In Laser-SNMS experiments, the sample is bombarded with a finely focused pulsed primary ion beam (see Section 3.1.1.1.1). While the primary ion pulse is striking the target, voltages on the extraction electrodes are set so that electric fields retard positive secondary ions. After the primary ion pulse, the voltages are switched so that ions formed by laser post-ionization of the neutral particles in the sputtered cloud have significantly different energy than the secondary ions formed in the sputtering process. Ions are analyzed by a TOF mass spectrometer with an electrostatic energy analyzer or a reflectron which discriminates against the secondary ions. The TOF allows all photoions to be simultaneously measured in each laser shot.

Laser-SNMS imaging is performed by either scanning the ion beam over the sample or by translating the sample under a fixed ion beam. If an LMIS is used for sputtering, nanoanalysis down to 50 nm can be achieved. Charge compensation for analyses of insulators is possible by using pulsed low energy electrons, which are introduced during the time interval between sputtering pulses. Laser-SNMS depth profiles are obtained by sputtering the sample with a continuous ion beam and taking data with a pulsed ion beam in the center of the crater (dual-beam mode, see Section 3.1.2.2.1). In Laser-SNMS, as in other microprobe techniques (see Section 3.1.2.8), the combination of 2D imaging with depth-profile capabilities allows the visualization of the three-dimensional distribution of elements. However, the extremely high overall efficiency of R-Laser-SNMS (typically 3 – 8 % useful yield for most elements) permits the measurement of low concentrations of analytes in much smaller volumes, thus enabling higher lateral and depth resolution in these 3D visualizations. This capability could greatly contribute to the study of dopant and contaminant distributions in semiconductor devices.

Figure 70. Comparison between TOF-SIMS and Laser-SNMS

3.2.3.1.4. Ionization Schemes

As illustrated in Figure 71, several laser schemes can be used to ionize elements and molecules. Scheme (a) represents nonresonant ionization. Since the ionization cross section is very low, a very high laser intensity is required to saturate the ionization process. Scheme (b) shows a simple single-resonance scheme. This is the simplest but not necessarily the most desirable scheme for resonant post-ionization. Cross sections for (photo)ionization are much lower than those for resonant excitation steps; therefore, the photoionization laser intensity must be proportionally higher in order to efficiently ionize the atoms. High-intensity visible or UV laser beams can cause nonlinear ionization of interfering species, which is rarely a problem with high-intensity IR beams. Therefore, whenever selectivity is an issue, IR wavelengths for the photoionization step are preferable. Scheme (c) is the most versatile of the schemes shown, and it gives the best performance for metals: H, He, C, N, O, F, Ne, P, S, Cl, Ar, Br, Kr, I, Xe, and Rn cannot be analyzed using Scheme (c) with commercial laser systems and frequency upconversion in nonlinear crystals. Resonance ionization Scheme (d) can be used when an autoionizing structure exists in the ionization continuum. The cross section for autoionization is significantly larger than for normal photoionization; therefore, the intensity of the ionizing laser can be reduced. This allows the use of visible wavelengths without extensive nonlinear ionization of interfering species. Scheme (e) is used when even the lowest energy excited states of the analyte element require vacuum-UV (VUV) wavelengths. It differs from Scheme (c) only in the experimental method used to generate the wavelength for the first transition. For wavelengths below about 195 nm, either four-wave mixing or anti-Stokes Raman must be used. This makes Scheme (e) the most experimentally complex of the resonance ionization schemes. With this technique it is possible to measure the amount of ^{81}Kr (a radioactive isotope with approximately 1 part in 10^{18} natural abundance in the atmosphere) in a water sample after several isotope-enrichment steps [292]. Scheme (f) is generally used when the energy of the excited state structure is too high for Schemes (b), (c), or (d) and the experimental complexity of scheme (e) is to be avoided. Examples are C, N, O, P, S, Cl, Br, Kr, I, and Xe. The two-photon transition used in scheme (f) is a second-order process, which is why its cross section is quite low compared to the one-photon transitions of the other schemes. This means that high-intensity light is needed, and focusing of the laser beam is generally required. In fact, the intensity of the light needed for efficient two-photon excitation is usually sufficient to ionize the excited state, and so Scheme (f) often requires only a single wavelength. This experimental simplicity is counterbalanced by the fact that the high-intensity light can cause nonlinear processes, including multiphoton ionization, to occur in many other species, leading to interferences.

Isotope shifts for most elements are small in comparison to the bandwidth of the pulsed lasers

Figure 71. Schemes of laser post-ionization steps

used in resonance ionization experiments, and thus all the isotopes of the analyte will be essentially resonant with the laser. In this case, isotopic analysis is achieved with a mass spectrometer. Time-of-flight mass spectrometers are especially well-suited for isotopic analysis of ions produced by pulsed resonance ionization lasers since all the ions are detected on each pulse.

3.2.3.2. Instrumentation

A versatile Laser-SNMS instrument consists of a microfocus ion gun, a sputtering ion gun, a liquid-metal ion gun, a pulsed flood electron gun, a resonant laser system consisting of a pulsed Nd:YAG laser pumping two dye lasers, a non-resonant laser system consisting of a high-power excimer or Nd:YAG laser, a computer-controlled high-resolution sample manipulator on which samples can be cooled or heated, a video and electron imaging system, a vacuum lock for sample introduction, and a TOF mass spectrometer.

3.2.3.3. Spectral Information

Compared to electron impact on molecules, laser photoionization can be made to induce fragmentation of molecules to a much lesser extent by optimizing the laser parameters: intensity, pulse width and wavelength. This results in a higher degree of chemical information from Laser-SNMS spectra. On the other hand, significant multiple ionization of atoms typically occurs when using high laser powers to achieve high post-ionization rates.

3.2.3.4. Quantification

Only a portion of the neutral particles which is in the ionization volume (IV) of the laser beam is in principle available for the ionization. For this description the geometrical yield $Y_{\mathrm{IV}}(\mathrm{X}_i^0)$ is introduced (for notation, see Section 3.1.1.2):

$$Y_{\mathrm{IV}}\left(\mathrm{X}_i^0\right) = \frac{\text{No. of } \mathrm{X}_i^0 \text{ in the ionization volume}}{\text{No. of } \mathrm{X}_i^0} \tag{3.23}$$

Post-ionization occurs with probability $\alpha(\mathrm{X}_i^0 \rightarrow \mathrm{X}_j^{\oplus})$, where $\oplus$ denotes a photoion:

$$\alpha\left(\mathrm{X}_i^0 \rightarrow \mathrm{X}_j^{\oplus}\right) = \frac{\text{No. of generated } \mathrm{X}_j^{\oplus}}{\text{No. of } \mathrm{X}_i^0 \text{ in the interaction volume}} \tag{3.24}$$

Molecular particles can dissociate during the ionization process. This is taken into account by the different indices i and j.

For post-ionized particles, it is possible to define a generalized transformation probability $P^{\oplus}(\mathrm{A} \rightarrow \mathrm{X}_j^{\oplus})$:

$$P^{\oplus}\left(\mathrm{A} \rightarrow \mathrm{X}_j^{\oplus}\right) = \frac{\text{No. of generated } \mathrm{X}_j^{\oplus}}{\text{No. of sputtered } A} \tag{3.25}$$

$P^{\oplus}(\mathrm{A} \rightarrow \mathrm{X}_j^{\oplus})$ is given by Equation (3.26):

$$P^{\oplus}\left(\mathrm{A} \rightarrow \mathrm{X}_j^{\oplus}\right) = \sum_i P\left(\mathrm{A} \rightarrow \mathrm{X}_i^0\right) Y_{\mathrm{IV}}\left(\mathrm{X}_i^0\right) \alpha \left(\mathrm{X}_i^0 \rightarrow \mathrm{X}_j^{\oplus}\right) \quad (3.26)$$

The summation over i is necessary, because different precursors X_i^0 can be transformed into the same photoion $\mathrm{X}_j^{\oplus}$ by fragmentation.

For the detection of the generated ions particles $\mathrm{X}_i^{\mathrm{q}}$, the transmission $T(\mathrm{X}_i^{\mathrm{q}})$ of the mass spectrometer and the detection probability $D(\mathrm{X}_i^{\mathrm{q}})$ are considered in the same way as discussed in Section 3.1.1.2.

An important quantity is, again, the useful yield $Y_{\mathrm{u}}(\mathrm{A}, \mathrm{X}_i^{\oplus})$:

$$Y_{\mathrm{u}}\left(\mathrm{A}, \mathrm{X}_i^{\oplus}\right) = \frac{\text{No. of detected } \mathrm{X}_i^{\oplus}}{\text{No. of sputtered } A} \quad (3.27)$$

Values of $Y_{\mathrm{u}}(\mathrm{A}, \mathrm{X}_i^{\oplus})$ for elements typically range from 10^{-4} to 10^{-2} in the case of NR-Laser-SNMS, and from 10^{-2} to 10^{-1} in the case of R-Laser-SNMS. If the experimental parameters are not well known, the concentration of A can also be quantified by using the relative sensitivity factor (RSF) method [see Equations (3.8) and (3.9) in Section 3.1.1.2].

3.2.3.5. Applications

3.2.3.5.1. Nonresonant Laser-SNMS

Figure 72 [284] shows a typical NR-Laser-SNMS spectrum of a contaminated Si wafer under low dose sputtering conditions (primary ion fluence $< 10^{14}\ \mathrm{cm}^{-2}$). For post-ionization, the radiation of an excimer laser operating at a wavelength of 248 nm was focused into the sputtered plume (intensity $10^{10}\ \mathrm{W\,cm}^{-2}$). Since the ionization cross-section of Si at 248 nm is relatively low, the intensity of the matrix signals (Si, SiO) is lower than expected. Due to the use of a high-resolution TOF mass spectrometer (mass resolution $m/\Delta m = 3000$), the metal contaminants (Mn: 20 ppm, Ni: 130 ppm, Cu: 500 ppm, and Zn: 400 ppm) are clearly separated from the molecular signals at the same integral mass. The ultimate detection limits of NR-Laser-SNMS are given by the amount of available sample material and by the useful yield. If the outer monolayer is completely consumed within an area of $10^{-4}\ \mathrm{cm}^2$ and if the useful yield is $10^{-2} - 10^{-3}$, a surface coverage of about 10^7 atoms/cm^2 can be detected by at least 10 ions. This limit can only be reached if the corresponding ion signal is free of background and free of mass interferences. Table 6 presents the relative sensitivity factors $S(\mathrm{M}^+, \mathrm{Si}^+ + \mathrm{SiO}^+)$ with respect to the sum of the matrix signals Si^+ and SiO^+ and the detection limits (DL) determined for several metals on Si wafers by nonresonant postionization at 248 nm and 193 nm [284]. Due to the low matrix dependence of Laser-SNMS, the same sensitivity can be achieved for the detection of trace metals in matrices like polymers or large biomolecules as for semiconductor matrices.

Element mapping with nonresonant Laser-SNMS can be used to investigate the structure of electronic devices and to localize defects and microcontaminants [293]. Typical SNMS maps for a GaAs test pattern are shown in Figure 73. In the subscript of each map the number of counts per pixel is given. The images were acquired by using a 25 keV Ga^+ liquid-metal ion source with a spot size of about 150 – 200 nm. For the images shown only 1.5 % of a monolayer was consumed ("static SNMS").

Table 6. NR-Laser-SNMS: Relative sensitivity factors $S(\mathrm{M}, \Sigma\mathrm{Si})$ and detection limits DL for metals on Si wafer surfaces

Element	$S(\mathrm{M}, \Sigma\mathrm{Si})$		DL, atoms/cm^2	
	193 nm	248 nm	193 nm	248 nm
Al	0.9	0.9	8×10^9	3×10^{10}
Ti	1.9	9	5×10^9	5×10^9
V	2.1	42	3×10^8	3×10^8
Cr	2.9	28	3×10^9	3×10^9
Fe	1.6	31	5×10^9	5×10^9
Co	1.1	6.9	5×10^8	5×10^8
Ni	0.9	14	1×10^9	1×10^9
Cu	1.2	24	5×10^9	5×10^9
Ga	4.4	0.4	5×10^8	8×10^9
As	1.9	10	3×10^8	3×10^8
Mo	1.8	32	3×10^8	3×10^8
W	5.1	39	5×10^8	5×10^8

3.2.3.5.2. Resonant Laser-SNMS

Figure 74 shows Cu depth profiles obtained from silicon and 0.8-µm silicon oxide on silicon samples. For this experiment, half a silicon wafer without an SiO_2 layer and half a SiO_2-covered

Figure 72. A) Nonresonant Laser-SNMS spectrum of a Si wafer contaminated with various transition metals and hydrocarbons [284]. B) Detail of spectrum A)

Figure 73. Nonresonant Laser-SNMS mapping of a contact test structure on GaAs. Field of view $40 \times 40\,\mu m$ [293]

Si wafer were simultaneously implanted with 5×10^{14} ^{63}Cu atoms per square centimeter at 150 keV. For analysis, both samples were cooled to 107 K to reduce migration effects, and depth profiles were taken under the same experimental conditions. The integrated Cu signal for both samples, that is, the Cu sensitivity factor for Cu in silicon and for Cu in silicon oxide, was almost the same (a difference of less than 3 %, which is due to the differences in sputter yield), demonstrating the matrix independence and the quantification accuracy possible with R-Laser-SNMS. The dynamic range for ^{63}Cu is better than six orders of magnitude. Due to the limited mass discrimination of the implanter, 2 % ^{65}Cu is present. At the SiO_2 – Si interface, a higher Cu concentration was observed. The isotopic ratio at this pile-up near the interface and below is closer to that of natural copper, and this indicates that the sample was contaminated with Cu when the oxide was grown. The Cu profile in Si was broadened due to channeling effects which occur in crystalline silicon but not in amorphous silicon oxide [294]. The lowest measured signal corresponds to a concentration of 400 ppt, which is still not the detection limit.

Figure 75 shows R-Laser-SNMS images of copper concentration in the region of Te and Cd inclusions in a CdZnTe (CZT) film. It is clear from the images that the copper concentration is approximately 10 times higher in the Te inclusion (peak concentration approximately 50 ppb) than in the surrounding CZT matrix and approximately 500 times higher in the Cd inclusion. These data support the theory that the copper preferentially migrates to Te – Cd second-phase regions in the CZT matrix [295]. Further experiments must be performed to verify whether the solubility of Cu is much higher in Cd than in Te. The same imaging technique can be used to locate and quantify pharmaceutical products in tissue with subcellular resolution and sub-ppm detection limits [296].

R-Laser-SNMS can also be applied to detect Sn-labeled DNA at positively hybridized and unhybridized sites on a DNA biosensor chip, which can be used, for example, for genetic-disease and cancer diagnostics [297], [298]. DNA diagnostics by sequencing by hybridization (SBH) involve binding a small (typically 18 – 20-mer) oligonucleotide to a chip. The chip may be glass, silicon, gold, or platinum. The polymerase chain reaction is used to produce fragments of the genomic DNA with an attached label. The size of the fragment can vary from a few dozen to several hundred or several thousand nucleotides.

Figure 74. Depth profile of ^{63}Cu in Si and of ^{63}Cu and ^{65}Cu in SiO_2 [294]. Implantation parameter: 5×10^{14} ^{63}Cu atoms/cm^2 at 150 keV

Figure 76 shows a R-Laser-SNMS image of ^{118}Sn obtained from a DNA biosensor chip. For this experiment, two different 17-mer oligonucleotides were bound to platinum circles on a silicon wafer (three locations each). Enriched ^{118}Sn-labeled DNA which was completely complementary to one of these oligonucleotides and noncomplementary to the other was hybridized to this chip. After the hybridization, the sample was washed to remove unhybridized probes. The image shows three peaks at the complementary DNA sites. The discrimination between hybridized and unhybridized sites is better than 100. A single point on the top center spot was analyzed twice before the full image was taken, leading to a slight signal reduction. The same technique can be readily applied to a variety of problems in bioanalytical chemistry, such as screening of combinatorial libraries.

Figure 76. ^{118}Sn image of Sn-labeled DNA hybridized to six oligonucleotide spots, three of which were complimentary, and three noncomplementary

3.3. Ion-Scattering Techniques

3.3.1. Rutherford Backscattering Spectroscopy (RBS)

Rutherford backscattering spectroscopy is one of the most frequently used techniques for quantitative analysis of composition, thickness, and depth profiles of thin solid films or solid samples near the surface region. It has been in use since the 1960s and has evolved since then into a major materials-characterization technique. The number and range of applications are enormous. Because of its quantitative feature, RBS often serves as a standard for other techniques.

3.3.1.1. Principles

In RBS, a beam of monoenergetic ions, usually H^+ or He^+ of typical energy 0.5 – 2.5 MeV, is directed at a target, and the energies of the ions which are scattered backwards are analyzed. In the backscattering collision, energy is

transferred from the impinging particle to the stationary target atom. The energy ratio between the projectile energy E_1 after collision and the energy E_0 before collision, derived from binary collision theory, is [299], [300]:

$$\frac{E_1}{E_0} = K = \left[\frac{\left(M_2^2 - M_1^2 \sin^2\theta\right)^{1/2} + M_1 \cos\theta}{M_2 + M_1} \right]^2 \quad (3.28)$$

The energy ratio E_1/E_0, known as the kinematic factor K, shows that the energy after scattering depends only on the mass M_1 of the projectile, the mass M_2 of the target atom, and the scattering angle θ (i.e., the angle between incident and scattered beam). If the parameters M_1, E_0, and θ are known, M_2 may be determined and the target element identified.

For direct backscattering through 180°, the energy ratio has its lowest value given by:

$$\frac{E_1}{E_0} = \left(\frac{M_2 - M_1}{M_2 + M_1}\right)^2 \quad (3.29)$$

In the case $M_1 = M_2$, the incident particle is at rest after a central collision, and all the energy is transferred to the target atom. For target atoms with $M_2 < M_1$ no backscattering occurs.

The energy of the backscattered ion is given by Equation (3.28) only for scattering by an atom at the surface of the target. However, in RBS the ion beam penetrates the target, and an ion may be backscattered by target atoms at any point along its path. In the energy region used for RBS, the ion trajectory is a straight line (apart from the backscattering collision) along which the ions lose energy primarily through excitation and ionization of atomic electrons (electronic energy loss). The energy loss per unit path length dE/dx is called the stopping power. These additional energy losses broaden the peak observed in an RBS spectrum of a thin film.

The situation is illustrated in Figure 77. The upper part shows a thin film of Ni deposited on a Si substrate. Only particles scattered from the front surface of the Ni film have an energy given by the kinematic equation (Eq. 3.28), $E_1 = K_{Ni}E_0$. As particles traverse the solid, they lose energy along the incident path. Therefore, particles scattered from a Ni atom at the interface Si – Ni have an energy smaller than $K_{Ni}E_0$. On the outward path the particles lose again energy. On emerging from the surface, the particles scattered at the interface have a total energy difference ΔE relative to particles scattered at the surface, causing a broad peak in the backscattering spectrum. The peak width ΔE is related to the thickness of the Ni film (see below).

Figure 77. Schematic backscattering spectra for MeV He^+ ions incident on a 100 nm Ni film on Si (A) and after reaction to form Ni_2Si (B). Depth scales are indicated below the energy axes [299].

For Si atoms the kinematic factor is smaller ($K_{Si} < K_{Ni}$) due to their lower mass. Backscattered particles from Si atoms appear at lower energies in the spectrum. Because no Si atoms are at the surface, the energy spectrum produced by scattering from Si starts at an energy lower than $K_{Si}E_0$ and then extends to zero energy, since the Si atoms form a substrate of effectively infinite depth.

For a surface layer consisting of atoms with lower mass than the substrate atoms, the peak due to the surface layer merges with the broad continuum and appears as a small feature on top of it. For surface analysis by RBS, conditions

must be such that the mass of surface atoms is considerably higher than the mass of substrate atoms in order to resolve the peak due to surface atoms completely. Only under these circumstances is the sensitivity of RBS comparable to those AES and XPS, that is, up to ca. 10^{-3} atomic layers. No chemical information is available.

So far we have assumed that all the target atoms are equally accessible to the projectiles. In a single crystal, atomic rows and planes can guide energetic ions along the channels between rows and planes, so that the ion beam penetrates deeply into the crystal, an effect known as channeling [299–301]. Channeling occurs when the ion beam is carefully aligned with a major symmetry direction of the single crystal. Figure 78 shows a side view of this process in which most of the ion beam is steered through the channels formed by the strings of atoms. Channeled particles cannot get close enough to the atomic nuclei to undergo large-angle Rutherford scattering, and hence the scattering is drastically reduced by a factor of about 100. Atoms at the surface produce a surface peak in the backscattering spectrum because the ion beam is scattered from the surface atoms with the same intensity as from a random array of atoms. The second atom in each string of atoms is completely shadowed in a perfectly rigid lattice due to the "shadow cone" formed by the ion trajectories. Thus, channeling improves enormously the sensitivity of RBS to atoms at the surface.

Figure 78. Schematic of particle trajectories undergoing scattering at the surface and channeling within the crystal. The depth scale is compressed relative to the width of the channel in order to display the trajectories [299]

3.3.1.2. Instrumentation

Ion beams suitable for RBS are produced in particle accelerators. By far the most widely used device for the production of MeV ion beams is the Van de Graaff electrostatic accelerator, either single-ended or double-ended (tandem Van de Graaff). The reader is referred to [302] for detailed information about accelerator technology. Accelerators normally produce ions in several charge states, and even a multiplicity of species. To extract a beam suitable for materials analysis, the beam is passed into the field of an analyzing magnet. A mass and charge selected beam then enters an UHV environment via differentially pumped apertures and is steered to the target by electrostatic or magnetic lenses. The beam size at the target is typically 1 mm^2. Small beam spots, if desired, can be obtained by suitable lens systems. Selected area analysis using small spots is usually carried out by specimen manipulation. For general analysis the ions strike the specimen at normal incidence. When structural information is sought (RBS + channeling), the specimen is mounted on a multiple-axis manipulator and may be rotated about the point of ion impact to vary the angle of incidence about channeling directions.

The scattering angle for optimum mass resolution would be 180° (a certain ΔM_2 gives the largest change in K when $\theta = 180°$, Eq. 3.28). Because of the detector size, in practice $\theta \approx 170°$ is chosen. The backscattered ions are usually detected by a solid-state detector, either a silicon barrier detector or a passivated implanted planar silicon (PIPS) detector. For conventional RBS with He^+ or H^+ ions at 1 – 2 MeV the PIPS detector has the better energy resolution (about 10 keV compared to 15 keV for surface barrier detectors [303]). The detector signals, which exhibit good proportionality to the energy of the incident particles, are amplified and sorted in energy in a multichannel analyzer.

Increasing use has been made of medium-energy ions and of heavier ions to optimize certain features of backscattering analyses. *Medium energy ion scattering* (MEIS) employs ions with energies of 100 – 500 keV together with electrostatic analyzers or time-of-flight (TOF) detectors. MEIS offers very shallow analysis depth with resolution up to monolayers [304]. *Heavy ion backscattering spectroscopy* (HIBS) uses ions such as ^{12}C, ^{16}O, or ^{35}Cl together with TOF detectors to obtain extremely high sensitivities (ca. 10^9 atoms/cm^2) for trace analysis [305].

3.3.1.3. Spectral Information

An RBS spectrum contains information on the mass of the scattering atoms, the composition of a surface layer, the depth of scattering atoms, and thickness of a surface layer.

The evaluation of the mass of the target atoms from the energy of backscattered particles is described in Section 3.3.1.1. An example of the nature of the compositional information obtainable from an RBS spectrum is based on Figure 77. The lower part of the figure shows schematically aa Ni film on Si that has undergone reaction to form Ni_2Si. After reaction, the Ni signal ΔE_{Ni} has spread slightly due to the presence of Si atoms contributing to the energy loss. The Si signal shows a step at the energy $K_{Si}E_0$ corresponding to Si in the Ni_2Si. The hatched peak areas in the figure are a measure of the number of particles scattered by Si or Ni atoms. Since the probability of a collision between the projectile and a target atom is easily obtained (see Eq. 3.32), the number of Si and Ni atoms in the target and hence the composition N_{Ni}/N_{Si} may be calculated.

Given the composition of a layer, it is possible to establish a depth scale for an element distribution or to measure the layer thickness from the energy of the scattered particles. This depends on the energy loss of the projectile on its inward and outward paths, as described in Section 3.3.1.1. The difference in energy ΔE of a particle scattered at the surface and a particle scattered at a depth x is given by

$$\Delta E = [S]\,x \tag{3.30}$$

where $[S]$ is the energy loss factor, which depends on the stopping power on the inward and outward paths, the kinematic factor K, and the orientation of the sample to both the incident beam and the detector direction [300]. In Figure 77 the depth scales are indicated.

RBS together with channeling can be used to detect and measure the thickness of an amorphous layer on an otherwise crystalline substrate. The method is commonly used to obtain structural information on the damaged surface layer of ion-implanted semiconductors and to study the damage removal upon annealing. An example is shown in Figure 79 for GaAs [306]. If the incident ion beam is directed onto the GaAs crystal in a ⟨110⟩ channeling direction, the backscattering yield is drastically reduced (d) compared to the yield when the beam is incident in a nonchanneling or "random" direction (a). Note the small surface peak in the channeled spectrum. Ion implantation with 120 keV Si^+ ions to a dose of $5 \times 10^{15}\,cm^{-2}$ produced an amorphous surface layer in GaAs. Because no channeling is possible in this layer, the intensity of the backscattered signal under channeling conditions increases and is as high as in the random case. Ions passing through the amorphous layer experience the crystalline nature of GaAs, which results in a reduced backscattering yield (b). From the width of the broad peak in curve b the thickness of the amorphous layer was determined to be about 140 nm. After annealing at 950 °C the intensity of the backscattering yield under channeling conditions dropped substantially (c). The spectrum resembles closely that of crystalline GaAs, which indicates that the implantation damage is annealed out almost completely.

Figure 79. RBS spectra from GaAs implanted with silicon before and after annealing at 950 °C (120 keV Si^+ – GaAs, dose: $5 \times 10^{15}\,cm^{-2}$) [306]
Uppermost spectrum is taken in a nonchanneling direction; the others are in channeling directions

One of the most fascinating applications of channeling RBS is the study of lattice locations of impurity atoms. By measuring the angular de-

pendence of the backscattering yield of the impurity and host atoms around three independent channeling axes it is possible to calculate the position of the impurity. Details can be found in [301].

3.3.1.4. Quantification

For an ion beam with the total number Q of ions impinging on a thin film, the number Q_A of particles backscattered from atoms of type A and registered in the detector (also called yield Y_A), is given by:

$$Q_A = Y_A = Q N_A \sigma_A \Delta\Omega \tag{3.31}$$

where N_A is the areal density of atoms A in the film (atoms/cm^2), σ_A the differential scattering cross section (cm^2/sr), and $\Delta\Omega$ the solid angle of the detector. The differential scattering cross section describes the probability that a projectile is scattered by a target atom through an angle θ into a solid angle dΩ centered about θ. If the interaction potential between the particle (M_1, Z_1) and the target atom (M_2, Z_2) during scattering is given by the Coulomb potential, the cross section is given by the Rutherford formula:

$$\sigma(E,\theta) = \left(\frac{Z_1 Z_2 e^2}{4E}\right)^2 \cdot \frac{4\left[\left(M_2^2 - M_1^2 \sin^2\theta\right)^{1/2} + M_2 \cos\theta\right]^2}{M_2 \sin^4\theta \left(M_2^2 - M_1^2 \sin^2\theta\right)^{1/2}} \tag{3.32}$$

Equation (3.32) is given in cgs units. For practical calculations, the value $e^2 \approx 1.44 \times 10^{-13}$ MeV cm is useful. For standard RBS with 1 – 2-MeV He$^+$ ions, the use of the Rutherford cross section is justified (giving the technique its name). Deviations occur at both higher and lower energies [300].

For a particular primary ion and fixed experimental conditions, the scattering cross section is a function only of the mass and atomic number of the scattering atom, and can be calculated. Thus, in principle, all the terms in Equation (3.31), except for the required N_A, are known. Therefore, RBS is an absolute method that does not require the use of standards.

For a compound film $A_m B_n$, the composition may be calculated from Equation (3.31) to be:

$$\frac{n}{m} = \frac{N_B}{N_A} = \frac{Q_B \sigma_A(E,\theta)}{Q_A \sigma_B(E,\theta)} \tag{3.33}$$

Note that this ratio depends only on the ratio of measured yields Q_A/Q_B and knowledge of the cross section ratio σ_A/σ_B. The hard-to-measure quantities Q and $\Delta\Omega$ have cancelled.

For targets containing several elements which might produce overlapping peaks, RBS spectra are analyzed by computer simulations. The energy spectrum of the backscattered particles is calculated for the actual experimental parameters and an assumed target composition. Then the target composition is altered (either manually or by using a least-squares fitting procedure) until the calculated and measured spectra are closely matched. A widely used RBS analysis program is the RUMP code [307], [308]. Commercial software packages are also available [300].

The accuracy in RBS results is ca. 3 % for areal densities and better than 1 % for stoichiometric ratios. These high accuracies are only obtained when all relevant quantities are measured or evaluated carefully. Pitfalls which often prevent RBS from achieving its full accuracy are described in [309]. Calibration can be achieved by measuring standards obtained by either implanting into or depositing on a light element (silicon) a known amount of a much heavier element (e.g., Ta or Sb).

3.3.1.5. Applications

Since RBS is a major technique for the analysis of thin solid films and surface layers, and the number of published applications in these areas is enormous. The number of publications in which RBS has been used, either alone or together with other analytical techniques, is about 1000 per annum. The majority of applications are in the field of semiconductor technology. Ion-implantation damage and damage annealing, implantation profiles, multilayer systems grown by molecular beam epitaxy or chemical vapor deposition, silicide formation, and diffusion barriers for contacts are among the topics routinely investigated by RBS.

A typical example is the formation of a buried β-$FeSi_2$ layer in Si [310]. The system is a favorable one for RBS, since Fe is much heavier than

Si. The $FeSi_2$ was synthesized by implanting Fe to a high dose (2.7×10^{17} cm^{-2}) into Si and performing a high temperature annealing. $FeSi_2$ exists in different phases, which complicates the formation of the low-temperature semiconducting β-phase. After a short annealing (10 s) at 1150 °C, α-$FeSi_2$ is formed. The transformation to β-$FeSi_2$ is performed by prolonged annealing (17 h) at 800 °C, a temperature well below the $\alpha-\beta$ transition. Figure 80 shows the RBS spectra. The Si yield starts at the surface energy $K_{Si}E_0$ and shows a large dip at lower energies, whereas the Fe peak starts at energies below $K_{Fe}E_0$, which indicates that the $FeSi_2$ layer is buried below the Si surface. The difference in Fe signal heights for the α- and β-phases indicates a change in density during the phase transformation. It is estimated that the α-phase contains ca. 17 % structural vacancies. The channeling spectrum of the β-phase shows that the buried layer is crystallographically aligned with the Si [(001) planes of β-$FeSi_2$ are parallel or slightly off-oriented to (111) Si].

Figure 80. RBS spectra of buried α-$FeSi_2$ (full line) and β-$FeSi_2$ (dotted line) layers taken in random direction. The $\langle 111 \rangle$ channeling spectrum (circles) refers to the β-$FeSi_2$ layer [310].

RBS and channeling are extremely useful for the characterization of epitaxial layers. An example is the analysis of a $Si_{1-x}Ge_x - Si$ strained layer superlattice [311]. Four pairs of layers, each about 40 nm thick, were grown by molecular beam epitaxy on a (100) Si substrate. Because of the lattice mismatch between $Si_{1-x}Ge_x$ ($x \approx 0.2$) and Si, the $Si_{1-x}Ge_x$ layers are strained. Figure 81 shows RBS spectra in random and channeling directions. The four pairs of layers are clearly seen both in the Ge and Si yield. The spectrum for channeling in the $\langle 100 \rangle$ direction is typical, whereas a large dechanneling is observed in the $\langle 110 \rangle$ direction, due to the lattice distortion at the interface $Si_{1-x}Ge_x - Si$. (The strained $Si_{1-x}Ge_x$ layer grows such that the in-plane lattice constant is the same as that of Si, whereas the perpendicular lattice constant is larger. Therefore, $\langle 100 \rangle$ channels are rather undistorted and diagonal $\langle 110 \rangle$ channels are distorted by a small angle.) The large dechanneling yield is a direct consequence of the lattice strain. The distortion can be measured as a small angular shift in angular scans at energies corresponding to specific Si and $Si_{1-x}Ge_x$ layers. By applying high-resolution RBS, even the intermixing of Si and Ge during epitaxial growth has been studied [312].

Figure 81. RBS spectra of 2.07 MeV He^+ ions backscattered from a $Si_{1-x}Ge_x - Si$ strained layer superlattice. The full line refers to a random direction; the other spectra are taken along various channeling directions [311].

Other fields for RBS analysis include optical and dielectric materials, hard and protective coatings, superconductors, and magnetic materials.

As an extremely useful method for applied materials science RBS has also contributed to basic science. A well-known example is surface melting [313]. Figure 82 shows normalized backscattering yields of H^+ from Pb near the melting point in the $\langle 101 \rangle$ direction (double alignment). The surface peak increases with increasing temperature and develops into a broad peak at 600.5 K. At 600.8 K, just above the melting temperature (600.7 K), the random spectrum is obtained, as is expected for a bulk liquid.

The broad peak below the melting temperature (curve d) can be fitted by assuming a disordered liquid surface layer (M) plus a partially ordered transition layer (I) between the liquid and the crystalline substrate. These were the first direct measurements of surface melting. Later experiments showed that the surface melting is strongly dependent on the orientation of the surface.

Figure 82. Normalized backscattering yields of H^+ ions from Pb near the melting point, with the incident beam and scattered beam directed along ⟨101⟩ crystal axes (double alignment)
a) 295 K; b) 506 K; c) 561 K; d) 600.5 K; e) 600.8 K
Spectrum d was fitted by a sum of contributions M from a liquid surface layer, and I from a partially ordered transition layer [313]

3.3.2. Low-Energy Ion Scattering (LEIS)

3.3.2.1. Principles

In principle, a low-energy ion scattering (LEIS) experiment is like RBS at low energies: an ion beam is sent to a target at a large angle with respect to the surface plane, and backscattered projectiles are detected at a large scattering angle [314], [315]. In contrast to RBS, in a typical LEIS experiment only positive ions are detected. Consequently, the fraction of singly charged ions P^+, i.e., the yield of singly charged ions divided by the total backscattered yield, has to be included when calculating the ion yield Q_A^+ backscattered from an atom of species A:

$$Q_A^+ = Q_0 N_A \frac{d\sigma_A}{d\Omega} P^+ S T \Delta\Omega \tag{3.34}$$

where Q_0 is the number of incident projectiles, N_A the areal density of atoms A in the surface (atoms/cm^2), $d\sigma_A/d\Omega$ the differential scattering cross section, S a steric factor describing the influence of plural scattering, and T and $\Delta\Omega$ the transmission function and the solid angle of the spectrometer, respectively.

The scattering cross-section is considerably different from the Rutherford cross-section, since the distance of closest approach R_{min} is rather large at low energies. Thus, electronic screening of the interaction between the nuclei is important. The screened scattering potential $V(r)$ reads:

$$V(r) = V_C(r) + V_e(r) = V_C(r)\,\Phi(r/a) \tag{3.35}$$

where V_C and V_e are the potentials of the target nucleus and target electrons, respectively; $\Phi(r/a)$ is the screening function, which describes how the Coulomb potential is weakened by electronic screening; and Φ is a function of the reduced distance r/a, where the screening length a is characteristic of the ion – target combination. Within the Thomas – Fermi – Molière model [299], Φ and a are given by Equations (3.36):

$$\Phi(r/a) = \sum_{i=1}^{3} \delta_i \exp\left(\frac{-c_i r}{a}\right) \tag{3.36a}$$

$$a = \frac{0.8852 \cdot a_0}{\left(\sqrt{Z_1} + \sqrt{Z_2}\right)^{2/3}} \tag{3.36b}$$

where $a_0 = 0.529$ Å (Bohr radius), and the constants $\delta_1 = 0.35$, $\delta_2 = 0.55$, $\delta_3 = 0.1$, $c_1 = 0.3$, $c_2 = 1.2$, and $c_3 = 6$. Thus, the influence of screening is negligible for small distance ($\Phi \to 1$ for $r \to 0$) and limits the interaction to distances comparable to the screening length ($\Phi \to 0$ for $r >> a$).

From the screened potential, the scattering angle $\theta(b)$ that corresponds to a given impact parameter b is obtained by solving the scattering integral, that is, the general relationship $\theta(b)$ for an arbitrary central potential [316]. From $\theta(b)$, the differential scattering cross section is readily obtained:

$$\frac{d\sigma}{d\Omega} = \left|\frac{b}{\sin\theta}\frac{db}{d\theta}\right| \tag{3.37}$$

In Equation (3.34), the major unknown is the charge fraction P^+, which still is a subject of theoretical investigation [317]. The state-of-the-art knowledge is as follows: When noble gas ions are used as projectiles, the detection of backscattered positive ions leads to the extreme surface sensitivity that is typical for LEIS, since $P^+ > 0$ is observed only when the projectile is scattered by a surface atom (due to their large binding energy, the mean charge state of low energy noble gas ions in any matter is neutral).

When only two charge states (0, +1) are of relevance, there are two contributions to P^+:

1) Projectile ions that have escaped neutralization along their trajectory
2) Those which were neutralized on their incoming path, re-ionized in the surface collision, and remained in the charged state when they left the surface:

$$P^+ = P^+_{\mathrm{surv,in}} P^+_{\mathrm{surv,out}} + \left(1 - P^+_{\mathrm{surv,in}}\right) \cdot P_{\mathrm{ReI}} P^+_{\mathrm{surv,out}} \tag{3.38}$$

where $P^+_{\mathrm{surv,in}}$ and $P^+_{\mathrm{surv,out}}$ are the probabilities that the ion survives neutralization on the incoming and the outgoing paths, respectively, and P_{ReI} is the probability for reionization in a surface collision. P_{ReI} depends strongly on the distance of closest approach in the surface collision and on the detailed electronic structure of projectile and target atom, and it is more important at higher energies [318]. Therefore, at low energies the survivals usually dominate the charge fraction. As long as only one neutralization process (Auger or resonance process) dominates in the energy range of interest, the probability that the ion escapes neutralization P^+_{surv} is obtained from the transition rate $R(t)$ in transitions per second:

$$P^+_{\mathrm{surv}} = \exp\left[-\int \mathrm{d}t R(t)\right] \tag{3.39}$$

Taking into account that neutralization means tunneling of a target conduction electron to the ion, the time integral can easily be replaced by integration over the distance s from the surface by use of the identity $\mathrm{d}t = \mathrm{d}s/v_\perp$, where $v_\perp$ is the component of the ion velocity perpendicular to the surface. From this, the velocity dependence of the survival probability $P^+_{\mathrm{surv},l}$ is obtained:

$$P^+_{\mathrm{surv},l} = \exp\left[-\frac{1}{v_{l,\perp}} \int \mathrm{d}s R(t)\right] = \exp\left[-\frac{v_{\mathrm{c}}}{v_{l,\perp}}\right] \tag{3.40}$$

In Equation (3.40), l can mean in or out, taking into account that the ion velocity after scattering is reduced due to the recoil energy transferred to the target atom. v_{c} is obtained by integration of the transition rate along the trajectory and is a characteristic velocity, representative of the neutralization efficiency: large values of v_{c} correspond to strong neutralization.

From Equation (3.40) we can draw the following conclusions:

1) At high energies (small values of $1/v_\perp$) the ion fraction is high, since there is only a short time for neutralization
2) For a given geometry, the ion fraction decreases exponentially with the reciprocal velocity

These theoretical predictions were experimentally verified for numerous target materials (see Fig. 83 [319]). Note the pronounced difference in neutralization between carbon atoms in a carbide and in graphite. This is one of the rare examples where matrix effects are observed.

Figure 83. Ion fraction of ^{3}He and ^{4}He ions (open and full symbols, respectively) in LEIS from Cu and different types of C as a function of the sum of the reciprocal velocities of the incoming and the scattered ion [319]

3.3.2.2. Instrumentation

An RBS and a LEIS setup are compared in Table 7.

Table 7. Comparison of experimental setups for RBS and LEIS

RBS	LEIS
Accelerator	Ion source (< 5 keV)
Deflection magnet	Wien filter
PIPS detector	Electrostatic spectrometer or TOF spectrometer plus microchannel plate
H^+, He^+ ions	Noble gas ions (He^+, Ne^+)

Due to its lower beam energy, an LEIS ion source is much more compact than an accelerator for MeV ions, but it has the same purpose: to provide a beam of ions with well-defined energy and mass. In LEIS, the latter demand is fulfilled by a Wien filter that selects ions of one specific mass, like the deflection magnet in RBS. In LEIS, the energies of the ions are too low for PIPS detectors and would lead to a signal to noise ratio of less than unity. Therefore, a stack of microchannel plates is used to detect the ions in LEIS. The detection efficiency of the microchannel plates is included in the experimental transmission factor T in Equation (3.34).

The energy selection is performed either by an electrostatic analyzer or by a TOF spectrometer. Both types of spectrometer have advantages and disadvantages. In a TOF measurement, ions and neutrals are separated by a post-acceleration of the ions. Without post-acceleration, neutrals are also detected, thereby increasing the intensity by orders of magnitude; this usually leads, however, to the loss of surface sensitivity. For analysis of surface structures, however, this is not a problem, since there the shadow cones may be used to regain surface sensitivity (see below).

A conventional electrostatic spectrometer works only with ions and is therefore surface sensitive, but it has low efficiency, since only ions in a narrow energy window around a well-defined pass energy are detected simultaneously; the pass energy has to be scanned to acquire the spectrum. The detection efficiency can be increased by orders of magnitude by using a double-toroidal energy analyzer in combination with a position-sensitive detector, since such a system measures simultaneously an energy spectrum of backscattered ions in a larger energy window. Such a set-up, known as ERISS, has been developed at Eindhoven University [320] (see Fig. 84). ERISS allows static LEIS measurements (without noticeable damage), even at polymer surfaces (see below) for which the sputter rate even under LEIS conditions is very high.

Figure 84. Schematic diagram of the ERISS setup [320]

3.3.2.3. Information

The energy spectrum in LEIS contains two types of information: energy and ion yield.

Energy Information. In the discussion up to now we have only considered the typical LEIS experiment, that is large angles of incidence and of exit with respect to the surface plane. Under these conditions, quantitative composition analysis is generally possible, since the ion – target interaction can be considered as binary collision due to the absence of matrix effects (see below).

Surface composition analysis by LEIS is based on the use of noble gas ions as projectiles, making use of the superb surface sensitivity of LEIS in this case. A consequence of this surface sensitivity is that the LEIS energy spectrum consists of lines, one per element, if the masses differ sufficiently. The lines are narrow, since inelastic energy losses play a minor role here. Thus, the information on the atomic species present is deduced from the energy of the backscattered ions, which may be converted to the mass of the scattering center. (Fig. 85 [321]). Figure 85 shows that the mass range in which LEIS is sensitive depends on the projectile mass.

Figure 85. LEIS spectra obtained from an Os – Ru top layer dispenser cathode with 3-keV He, Ne, and Ar projectiles, respectively. The He spectrum demonstrates the absence of O on the undamaged cathode surface, the inset of the He spectrum was obtained for a cathode exposed to 20 Langmuir oxygen at room temperature [321].

Yield Information. As can be seen from Equation (3.34), the backscattered ion yield in LEIS is a measure of the concentration of a certain element in the surface, if the other quantities are known. This is generally the case: the scattering cross section can be calculated along the lines of Equations (3.36) and (3.37) or found in tabulations; S is less problematic for large angles of incidence and exit (and may be considered constant); the transmission probability T is proportional to E for any electrostatic spectrometer that varies the pass energy (as long as the detection efficiency is energy-independent); the solid angle $\delta\Omega$ of the spectrometer can be assumed constant. Hence, for fixed experimental conditions (constant primary energy, constant geometry etc.), Equation (3.34) may be simplified to:

$$Q_A^+ = \eta_A c_A \tag{3.41}$$

where η_A is the sensitivity factor which contains all element specific quantities, and c_A is the concentration of element A in the surface.

In Figure 86, LEIS spectra are shown for two completely different types of Al_2O_3 samples, that is, α-alumina (sapphire) and γ-alumina powder with high specific surface area. Very similar results were obtained in both cases after thermal treatment at 400 °C [322]. The lowering of the Al signal in γ-alumina was ascribed to shielding by hydroxyl groups, which are typical adsorbates on γ-alumina.

Figure 86. LEIS obtained from different types of alumina with 3-keV He ions [322]

Figure 87. Different experimental geometries for low-energy ion spectroscopies

When measuring LEIS at small angles to the surface, both, for the incoming and for the outgoing particles, information on atomic structure may be obtained for a given surface (see Fig. 87). Both TOF-SARS and ICISS make use of the shadow cone and of focusing the enhanced ion intensity at the shadow onto the neighboring atom (see below): at glancing incidence, all surface atoms are hidden in the shadow cone of the first atom in a plane or terrace, and the scattered intensity is low; when the angle of incidence

is increased (with respect to the surface), at a critical angle the neighboring atoms leave the shadow cone and are hit by an enhanced flux of projectiles, which leads to a peak in the scattered intensity as a function of the angle of incidence (see below).

3.3.2.4. Quantification

The usefulness of Equation (3.41) depends crucially on whether or not the sensitivity factor η_A depends on the presence of other elements in the surface ("matrix effects"). It is an experimental finding that neutralization generally depends only on the atomic number of the scattering center, and matrix effects rarely occur. An instructive example is the neutralization of He by Al in the pure metal and in alumina. The slopes of the neutralization curves turn out to be the same in these two cases, that is, matrix effects are absent [323]. This is a strong indication that in the neutralization process not only the valence/conduction electrons, but also atomic levels below the valence/conduction band are involved.

Figure 88. Peak intensities of Nb and Ta versus the oxygen peak intensity for adsorption of oxygen on the pure metals [324]

From a practical point of view, it is more convenient to measure intensity ratios instead of absolute intensities. Thus, for example, Cu can serve as a reference material, relative to which the ion intensities backscattered from the atoms of the surface under consideration are measured:

$$\frac{Q_A^+}{Q_{Cu}^+} = \frac{\eta_A c_A}{\eta_{Cu}} \tag{3.42}$$

A further example where quantitative surface composition analysis is possible for a nontrivial surface is shown in Figure 88, where for the systems Ta + O and Nb + O adsorption, the ion signal from the metal is shown as a function of the ion signal from O. In this binary case the following concentration equations hold:

$$c_{Ta} + c_O = 1 \tag{3.43a}$$

$$c_{Nb} + c_O = 1 \tag{3.43b}$$

Inserting Equations (3.43) into Equation (3.42) yields:

$$Q_O^+ = \eta_O - Q_{Ta}^+ \frac{\eta_O}{\eta_{Ta}} \tag{3.44}$$

From Equation (3.44), one expects a linear relationship between Q_O^+ and Q_{Ta}^+, Q_{Nb}^+. Indeed, this is experimentally observed (see Fig. 88 [324]).

3.3.2.5. Applications

Applications of LEIS are widespread, going far beyond the needs of a typical surface-science laboratory, since LEIS is also capable of yielding information on insulating samples and on very rough structures (e.g., catalysts). The main problem with rough insulating surfaces is that they need charge neutralization (flooding by thermal electrons which neutralize the charging of the surface by incoming ions and emitted energetic electrons).

An example is a LEIS study on a specific spinel, namely, $ZnAl_2O_4$, for which cations (Zn) in tetrahedral sites are expected [325] to be less stable and therefore move to sites below the surface where they are better shielded, yielding a lower LEIS signal. This was confirmed by Brongersma et al [326] (Fig. 89. This figure shows that LEIS is very sensitive to Zn, as shown by LEIS from ZnO, but for the spinel no Zn is visible in the surface.)

Figure 89. LEIS spectra of 3 keV He^+ scattering from $ZnAl_2O_4$ (solid line) and from ZnO (dashed line) [326]

Figure 90. A) LEIS spectra of the $^{63}Cu-^{68}ZnO-SiO_2$ catalyst obtained with 5-keV Ne^+ ions for different doses (see inset, spectra are shifted vertically for clarity). Catalyst reduction temperature 700 K. Solid lines: fitted Gauss peaks [327]
B) The relative coverage of Cu and ZnO on the silica-supported catalyst, reduced at 700 K, as a function of the ion dose [327]

An even more ambitious goal is to characterize an unsupported catalyst, since in this case the surface is extremely rough, and the target rapidly deteriorates under bombardment: energy deposition leads to an enormous erosion, since the substrate cannot dispose of the energy deposited due to the the low thermal conductivity. As a consequence, static LEIS conditions have to be applied to obtain information on the surface alone. Figure 90 A shows a series of LEIS spectra obtained with 5-keV Ne^+ ions on a $^{63}Cu-^{68}ZnO-SiO_2$ catalyst, reduced at 700 K [327]. These LEIS spectra were obtained at ion doses of 3×10^{14}, 3.41×10^{15}, and $8.67 \times 10^{15}\ cm^{-2}$, respectively. Due to the use of isotopically enriched Cu and Zn, and of Ne^+ ions as projectiles, Cu and Zn can clearly be separated in the LEIS spectrum. A strong dose dependence is seen. Figure 90 B shows the dose-dependent surface concentrations of Cu and Zn. At low doses ($< 1.5 \times 10^{14}\ cm^{-2}$) the Zn concentration remains constant, while the Cu concentration increases. At these low doses, a hydroxyl layer on top of the catalyst is sputtered. The Zn signal stays constant despite removal of the adsorbate, indicating that at the virgin surface the Zn concentration was even higher.

As a final application, the analysis of a surface structure by TOF-SARS is discussed (for a general discussion, see [328]). Figure 91 shows that the scattered intensity is increased when projectiles hit a surface at the critical angle of incidence α_c due to focusing of collisions onto one of the neighboring atoms in the surface (A) or below the surface (B). Note that also recoiling atoms can be emitted in the same direction. Figure 92 a TOF spectrum is shown, measured for bombardment of CdS(0001) by 4 keV Kr^+ ions [329]. Also a spectrum of Ne projectiles scattered by Cd in CdS is shown as a function of the angle of incidence α. The peak around $\alpha \approx 20°$ is due to focusing of the projectiles by first-layer Cd atoms onto their first layer Cd neighbors, by which they are scattered into the detector. The peak at $\alpha \approx 65°$ is due to focusing of the projectiles by first-layer Cd atoms onto their second-layer Cd neighbors, by which they are scattered into the detector. Analysis of these critical angles permits the lateral first-layer interatomic spacings and the first-second interlayer spacing to be determined (see Fig. 91).

Figure 91. Schematic illustration of projectile trajectories, showing focusing collisions when the projectiles impinge at a critical angle α_c [330]

Figure 92. Schematic of a TOF-SARS experiment and examples of TOF-SARS spectra for Kr scattering from CdS: TOF spectrum; scans of the angle of incidence α and the azimuthal angle δ [329]

Finally, Figure 92 shows an azimuthal scan, again for CdS(0001) and Kr^+ ions incident at a grazing angle. This allows one to determine the surface periodicity, since the scattered intensity is minimal for incidence along the crystallographic axes, again because of shadowing. The intensity rises when the direction of incidence is tilted with respect to the crystallographic axis by a critical angle. The widths of the minima are related to the interatomic spacings along the particular directions. Wide, deep minima are expected for short interatomic spacings, because of the large azimuthal tilt needed to move the neighboring atom out of the shadow cone.

3.4. Other Ion-Detecting Techniques

3.4.1. Desorption Methods

3.4.1.1. Electron-Stimulated Desorption (ESD) and Electron-Stimulated Desorption Ion Angular Distribution (ESDIAD)

Electron irradiation of a surface, particularly one covered with one or more adsorbed species, can give rise to many types of secondary particles, including positive and negative ions. In ESD and ESDIAD, the surface is irradiated with electrons of energies in the range of 100 – 1000 eV, and the ejected positive-ion currents of selected species are measured in a mass spectrometer. If the angular distribution of the secondary ions is also measured, either by display on a screen or by using position-sensitive detection, then electron-stimulated desorption (ESD) becomes electron-stimulated desorption ion angular distribution (ESDIAD).

The electron desorption techniques are not used, and probably cannot be used, for compositional analysis, but they provide valuable information on the nature of electronic interactions leading to the breaking of bonds and, in the angle-resolved form, on the geometry of surface molecules and the orientation of broken bonds. The primary electrons do not, at the energies employed, succeed in breaking molecular or surface-to-molecule bonds or in knocking ions out of the surface directly, but the process is one of initial electronic excitation. An electron is absorbed by a surface – adsorbate complex or an adsorbed molecule itself, leading to excitation to an excited state by a Franck – Condon process. If the excited state is antibonding and the molecule or radical is already far enough

from the surface, desorption can occur. Since return to the ground state after excitation is a much more probable process, the cross sections for ion desorption are low ($10^{-20} - 10^{-23}$ cm^2). If core-level ionization is involved in the initial interaction with the incident electron, rather than valence levels as in the Franck – Condon-type excitation, then a desorption mechanism based on Auger decay has been proposed. The core level left behind after interatomic Auger decay creates a positive ion, which is then expelled by the repulsive Madelung potential.

The most common ions observed as a result of electron-stimulated desorption are atomic (e.g., H^+, O^+, F^+), but molecular ions such as OH^+, CO^+, H_2O^+, and CO_2^+ can also be found in significant quantities following adsorption of H_2O, CO, CO_2, etc. Substrate metal ions have never been observed, and this means that ESD is not applicable for surface compositional analysis. The most important application of ESD in the angularly resolved form ESDIAD is in determining the structure and mode of adsorption of adsorbed species. This derives from the fact that the ejection of positive ions in ESD is not isotropic. Instead the ions desorb along certain directions only, characterized by the orientation of the molecular bonds that are broken by electron excitation.

3.4.1.2. Thermal Desorption Spectroscopy (TDS)

Thermal desorption spectroscopy (TDS), sometimes called temperature-programmed desorption (TPD), is simple in principle. A gas or mixture of gases is allowed to be adsorbed on a clean metal foil for a chosen length of time; then, after the gas has been pumped away, the foil is heated at a strictly linear rate to a high temperature, during which the current of a particular ion or group of ions is monitored as a function of temperature. The ion masses are selected in a quadrupole mass spectrometer. As the binding energy thresholds of the adsorbed species on the surface are crossed, peaks in the desorbed ion current appear at characteristic temperatures. From the characteristic temperatures and the shape of the desorption peak above the threshold, the activation energies for desorption can be obtained, along with information about the nature of the desorption process. The mass spectrum from the mass spectrometer provides information about the species that actually exist on the surface after adsorption.

Although simple in principle, experimental artifacts that are possible in TDS must be avoided. Thus, ions accepted by the mass spectrometer must originate only from the surface of the foil, and in addition, the temperature distribution across the foil should be uniform to avoid the overlapping of desorption processes occurring at different temperatures. To ensure that these experimental requirements are met, the angle of acceptance into the spectrometer is restricted by placing a drift tube with an aperture between the foil and the spectrometer, and the foil itself is usually in the form of a long thin ribbon, from whose center section only are ions accepted. In addition, the heating rate must be sufficiently fast that the desorbed species accepted into the mass spectrometer is characteristic of the desorption process, but not so fast that the pressure rise around the foil is too great.

With correct experimental procedure, TDS is straightforward to use and has been applied extensively in basic experiments concerned with the nature of reactions between pure gases and clean solid surfaces. The majority of these applications have been catalysis related (i.e., performed on surfaces acting as models for catalysts), and in every case TDS has been used with other techniques such as UPS, ELS, AES, and LEED. To a certain extent it is quantifiable, in that the area under a desorption peak is proportional to the number of ions of that species desorbed in that temperature range, but measurement of the area is not always easy if several processes overlap.

3.4.2. Glow Discharge Mass Spectroscopy (GDMS)

In GDMS the surface to be analyzed is sputtered by a glow discharge in which the surface is the cathode, and the contribution to the sputtered flux of secondary neutrals is measured. On entering the discharge region, many of the sputtered atoms are ionized. The ions are then extracted from the discharge and passed via differential pumping stages into a region at much lower pressure where they can be mass analyzed.

Either magnetic or quadrupole mass spectrometers are used for mass analysis.

Like SSIMS and GDOS, GDMS has been developed commercially and has also had wide industrial application. Most of the applications have, like GDOS, consisted of rapid profiling of surface films many micrometers thick, with special emphasis on the depth distribution of trace elements, and would not be regarded as surface specific. Nevertheless, again like GDOS, GDMS is in principle a surface-specific technique and has occasionally been used in an ultrahigh-vacuum system and at very low erosion rates.

One of the attractions of GDMS is the relative ease and accuracy of quantification by using standard materials and relative sensitivity factors. For most elements, particularly the metallic and semiconducting elements, the spread of sensitivity factors is less than an order of magnitude, comparable to the situation in XPS. In addition, the actual sensitivities are significantly higher than in XPS or AES, with analysis at the part-per-million level being routine and at the part-per-billion level being quite possible.

3.4.3. Fast Atom Bombardment Mass Spectroscopy (FABMS)

Fast-atom bombardment mass spectrometry is very similar to SSIMS in practice, the only difference being that instead of using positively charged ions as the primary probe, a beam of energetic neutral atoms is used. Secondary ions are emitted as in SSIMS and analyzed in a mass spectrometer, usually of the quadrupole type. The beam of fast atoms is produced by passing a beam of ions through a charge-transfer cell, which consists of a small volume filled with argon to a pressure of about 10^2 Pa. Charge transfer occurs through resonance between fast argon ions and argon atoms with thermal energy, with efficiencies of 15 – 20 % if geometric and pressure conditions are optimized. Residual ions are removed by electrostatic deflection.

FABMS has two advantages over SSIMS, both arising from the use of neutral rather than charged particles. Firstly, little or no surface charging of insulating materials occurs, so that organics such as polymers can be analyzed without the need to employ auxiliary electron irradiation to neutralize surface charge. Secondly, the extent of beam damage to a surface, for the same particle flux, is much lower using FABMS than SSIMS, thus allowing materials such as inorganic compounds, glasses, and polymers to be analyzed with less worry about damage introducing ambiguity into the analysis.

3.4.4. Atom Probe Microscopy

The atom *probe field-ion microscope* (APFIM) and its subsequent developments, the *position-sensitive atom probe* (POSAP) and the *pulsed laser atom probe* (PLAP), have the ultimate sensitivity in compositional analysis (i.e., single atoms). FIM is purely an imaging technique in which the specimen in the form of a needle with a very fine point (radius 10 – 100 nm) is at low temperature (liquid nitrogen or helium) and surrounded by a noble gas (He, Ne, or Ar) at $10^{-2} - 10^{-3}$ Pa. A fluorescent screen or a microchannel plate is situated a few centimeters from the needle. A high positive voltage is applied to the needle, which causes noble-gas atoms approaching the needle to be ionized over points of local field enhancement (i.e., over prominent atoms at the surface); the ions are then repelled from these points and travel in straight lines to the screen or plate, where an atomic image of the needle tip is formed. This is called a field-ion image, and the voltage at which the image is optimized is called the *best imaging voltage.* The latter is in the range 5 – 20 kV.

3.4.4.1. Atom Probe Field-Ion Microscopy (APFIM)

If the voltage is raised further above the imaging voltage, the cohesive energy that binds atoms to the surface can be exceeded, and atoms can be removed by what is termed *field evaporation.* The evaporation field required is a function of the sample material and the crystallographic orientation of the needle. The removal of atoms is the basis of APFIM and its daughter techniques. If the evaporation field is pulsed with very short ($\leq$ 10 ns) voltage pulses of extremely sharp rise times ($\approx$1 ns), and the time taken for a field-evaporated atom to travel from the tip to a detector is measured, then the mass-to-charge ratio

of the ionized atom can be established; that is, elemental identification of the individual atom is possible. The region on the tip from which atoms are removed is selected by rotating or tilting the tip until the desired region, as viewed in the FIM image, falls over an aperture of about 2 mm diameter in the fluorescent screen. Most field-evaporated atoms will strike the screen, but those from the selected area will pass through the aperture into the time-of-flight mass spectrometer. For an aperture of 2 mm, the area analyzed on the tip is ca. 2-nm in diameter.

3.4.4.2. Position-Sensitive Atom Probe (POSAP)

Pulsed operation of the APFIM leads to analysis of all atoms within a volume consisting of a cylinder of ca. 2 nm diameter along the axis of the tip and aperture, with single atomic layer depth resolution but no indication of just where within that volume any particular atom originated. The advent of position-sensitive detectors has allowed APFIM to be extended so that three-dimensional compositional variations within the analyzed volume can be determined. This development is called position-sensitive atom probe (POSAP). The aperture and single-ion detector of APFIM are replaced by a wide-angle double channel plate, with a position-sensitive anode just behind the plate. Field- or laser-evaporated ions strike the channel plate, releasing an electron cascade, which is accelerated toward the anode. The impact position is located by the division of electric charge between three wedge-and-strip electrodes. From this position the point of origin of the ion on the tip surface can be determined, since the ion trajectories are radial. Thus after many evaporation pulses, leading to removal of a volume of material from the tip, both the identities and the positions of all atoms within that volume can be mapped in three dimensions. Because an evaporated volume may contain many thousands of atoms, the data collection and handling capabilities must be particularly sophisticated. POSAP is the only technique available for identifying and locating precipitates, second phases, particles, and interfaces on an atomic scale, and has therefore had considerable application in metallurgical and semiconductor problems.

Figure 93. Interference of the incoming and the reflected X-ray waves in the triangular region above a flat and thick reflecting substrate. The strength of the electromagnetic field is represented on the gray scale with instantaneous crests (white) and troughs (black). In the course of time, the pattern moves from left to right [352].

4. Photon Detection

4.1. Total-Reflection X-ray Fluorescence Analysis (TXRF)

4.1.1. Principles

Less than two decades after the first practical application of X-ray fluorescence [331], Moseley established the relation between the reciprocal wavelength of emitted characteristic X-ray fluorescence (XRF) and the atomic number Z of the elements [332], [333]. However, the XRF arrangement was not sensitive enough for trace or ultratrace analyses. Compton reported in 1923 that the reflectivity of a flat target increases below a critical angle of 0.1° under conditions of total X-ray reflection. The high reflectivity of the sample support reduced the spectral background of the support and improved the detection limit (DL) down to picogram levels in the early 1970s, when Yoneda and Horiuchi applied the principle of TXRF mainly to ultratrace elemental microanalyses of biological samples [334]. For more details on the history of TXRF, see [335–337].

Since then, TXRF has become a standard tool of surface and subsurface microanalysis [338–342]. In 1983, Becker reported on the angular dependence of X-ray fluorescence intensities in the range of total reflection [343]. Further development in the field of TXRF are improved detection limits [344] in combination with subtle surface-preparation techniques [345], [346], analyte concentrations extended even to ultratraces

Figure 94. Incident, reflected, and refracted beam at the interface of two media 1 and 2. On the left, medium 2 is optically denser than medium 1 ($n_2 > n_1$); on the right, it is vice versa ($n_1 > n_2$) [352].

(pg) of light elements such as Al [347], speciation of different chemical states [348] and novel optical arrangements [349] and X-ray sources [350], [351].

For information on both the history and principles of and future trends in XRF, see → X-Ray Fluorescence Spectrometry. For TXRF, see the handbook by KLOCKENKÄMPER [352] and current reviews [353–355].

Figure 95. Signal intensity of a thick, flat, and smooth Si substrate (—-), calculated for an impinging $Mo_{K\alpha}$ beam. In addition, the reflectivity R (·····) is shown as function of the glancing angle α. Below $\alpha_{crit} = 0.102°$, total reflection occurs with a stepwise increase in reflectivity and a stepwise decrease in signal intensity. The oblique dashed line represents the intensity from a rough Si substrate [352].

The basis of XRF analysis is the photoelectric absorption and the subsequent emission of X-ray photons characteristic of the fingerprints of analyte atoms in the sample. Element composition can be quantified by the relative intensities of the individual element fingerprints. In a TXRF arrangement, however, the primary beam interacts with the surface analyte atoms as a standing wave field (Fig. 93) and excites surface atoms rather than the bulk, in contrast to XRF. The emitted intensity is directly proportional to the intensity of the standing wave field. In the subsurface, the primary beam generates an evanescent wave field. Hence, the characteristic fluorescence of analyte atoms is a response to these varying excitations by the standing and evanescent wave fields, and its dependence upon the glancing angle can be exploited for stratigraphy of parallel-layered structures and for distinguishing particulate from film-type surface contamination.

In X-ray spectrometry, attenuation, deflection, and interference must be considered. Attenuation is described by the well-known Lambert – Beer law and the mass attenuation coefficient as given for conventional XRF.

Practical X-ray energies do not exceed 100 keV. The primary beam is mainly attenuated by the photoelectric effect. Scattering, both elastic (Rayleigh) and inelastic (Compton), represents a minor contribution to attenuation at energies below 100 keV.

Reflection and refraction of X-rays follow the laws of optics (Fig. 94): The glancing angles of incidence (α_1) and reflection (α_1^*) are equal. The respective refraction angles follow SNELL's law for different phase velocities v in media 1 and 2:

$$v_2 \cos\alpha_1 = v_1 \cos\alpha_2 \tag{4.1}$$

When the glancing angle α_2 of the refractive beam becomes zero, the refractive beam runs tangential to the boundary surface. Below the

critical glancing angle of incidence, reflectivity increases to 100 % and the penetration, and hence information, depth is limited to a few nanometers. Reflection below the critical angle is defined as total reflection. The critical angle α_{crit} depends on the photon energy E and the atomic mass M of the medium, its atomic number Z, and its density ϱ (Eq. 4.2). The signal intensity is also a function of surface roughness.

$$\alpha_{\mathrm{crit}} \approx \frac{1.65}{E} \sqrt{\frac{Z\varrho}{M}} \tag{4.2}$$

At α_{crit} the penetration depth approaches a minimum, particularly in the case of reflective surfaces, such as chemo-mechanically polished Si. Total reflection disappears on rough surfaces (Fig. 95). Below α_{crit} penetration depth is in the range of a few nanometers (Fig. 96).

Figure 96. Penetration depth z_{n} of X-rays impinging on silicon at a variable glancing angles α_1. The curves were calculated for three different photon energies. The dashed vertical line represents the respective critical angle [352].

4.1.2. Instrumentation

The construction of a TXRF system, including X-ray source, energy-dispersive detector, and pulse-processing electronics, is similar to that of conventional XRF. In addition, the geometric arrangement must provide for total reflection of a monochromatic primary beam. The totally reflected beam interferes with the incident primary beam. This interference causes the formation of standing waves above the surface of a homogeneous sample, as depicted in Figure 93, or within a multiple-layered sample. A part of the primary beam fades away in an evanescent wave field in the bulk or substrate [359].

A TXRF instrument (Fig. 97) consists of an X-ray source, a low-pass filter, collimator, monochromator, sample holder, detector and an electronic registration unit. Various target materials (e.g., Mo, W, or Mo – W) alloys are used in fine-focus, sealed-anode X-ray tubes powered by a water-cooled 3.5 kW generator. Maximum permissible power for high-Z anodes is about 2 – 3 kW. During their lifetime of 2000 – 4000 h, they gradually lose intensity. Rotating anodes are warranted for 2000 h of operation at higher operating powers of up to 30 kW and more intense water cooling (15 L/min instead of 5 L/min).

Figure 97. Schematic of a TXRF system equipped with a fine-focused anode

A double reflector is used as low-pass filter [340]. Tunable monochromators in combination with alloy anodes are also commercially available. For sensitive surface analyses monochromators are necessary. They are made of LiF, highly oriented pyrolytic graphite (HOPG), or multilayers of W – Si, W – C, or Mo – B_4C, which provide for intense and monochromatic radiation, preferentially $W_{L\beta}$ or $Mo_{K\alpha}$. The sample positioning device must operate at high geometrical reproducibility in all three dimensions, with automated sample load and unload stations. The sample must be in an evacuated or He-flushed chamber to avoid disturbing absorption by air.

The energy-dispersive (EDX) solid-state detector (SSD, Figs. 98 and 99) is made of lithium-drifted Si crystal [Si(Li)]. Between thin p- and n-type layer lies a high-resistivity Si crystal of centimeter dimensions. The front and end planes of the crystal are coated with Au and serve as electrodes. The crystal, cooled to 77 K by liquid

nitrogen, represents a $p-i-n$ diode (Fig. 99). An incident X-ray photon with an energy above 2 keV causes a cascade of photoelectron – hole pairs into which the initial photon energy is completely converted. Due to the reverse bias, electrons rapidly drift to the positively polarized n-type electrode, and holes to the negative p-type electrode. The number of electron – hole pairs is proportional to the energy of the impinging photon; hence, the charge pulse is a measure of the characteristic photon energy. Finally, the X-ray spectrum is established by a multichannel analyzer which distributes the pulses according to their height into a series of channels, each of which is reserved for a small range of pulse heights (i.e., energies), and adds them up to give the measured intensity.

Figure 98. Section drawing of the front end of an SSD with a grooved Si(Li) crystal. Crystal and preamplifier are connected to a cooled copper rod and shielded by a case with an end cap and Be window [352], [360].

Optimal resolution, that is,low full width at half-maximum (FWHM), is a trade-off between high count rate, i.e., low dead-time, and good spectral resolution.

Silicon drift detectors (SDDs, Figs. 100 and 101) now also provide sufficient resolution (FWHM = 0.175 keV) for sample spots of size 2×2 to 100×100 mm, and enable high-speed operation ($> 10^5$ counts/s). SDD can be combined with microelectronics and applied in portable TXRF models for microanalytical applications [361]. They must be cooled by a Peltier element.

Figure 99. Semiconductor detector operated as a pin diode with a reverse voltage or bias. An incident X-ray photon ultimately produces a series of electron – hole pairs. They are swept out by the bias field of − 500 V: electrons in the direction of the n-layer, and holes in the direction of the p-layer. Thus, a small charge pulse is produced (after [361]).

4.1.3. Spectral Information

Spectral information from TXRF spectra is similar to conventional XRF-EDX spectra. The analyst must be always aware of potential spectral interferences that cannot be resolved with standard EDX detectors [347]. Spurious peaks can be assigned to escape peaks in energy dispersive spectra. An escape peak emerges when intense fluorescence of sufficiently high energy (giving rise to the *mother peak*) impinges on the SSD, expelling, as usual, photoelectrons from Si core shells. Excited Si atoms emit X-ray photons that are usually reabsorbed by the crystal. Photoelectrons generated by these photons initiate additional electron – hole cascades (i.e., charge pulses) in the same way as the sample fluorescence. However, photons near the SSD crystal surface also escape without producing a pulse, thus carrying off the difference between the energy of the mother peak and the generated core photoelectron. This "escaped" energy gives rise to a separate, low-energy *daughter peak*. Some elements whose Kα peaks interfere with escape peaks of other elements in SSDs or SDDs are listed in Table 8.

Figure 100. Schematic view of a cylindrical silicon drift detector (SDD) [361]

Table 8. Some elements whose Kα peaks interfere with escape peaks of other elements in SSDs or SDDs [347]

Elements	Escape peaks
V	$Co_{K\alpha}$, $Mn_{K\beta}$, $Dy_{L\alpha}$, $Ho_{L\alpha}$, $Er_{L\alpha}$, $Gd_{L\beta}$
Cr	$Co_{K\alpha}$, $Fe_{K\beta}$, $Er_{L\alpha}$, $Tm_{L\alpha}$, $Tb_{L\beta}$, $Dy_{L\beta}$
Mn	$Ni_{K\alpha}$, $Co_{K\beta}$, $Yb_{L\alpha}$, $Lu_{L\alpha}$, $Hf_{L\alpha}$, $Ho_{L\beta}$
Fe	$Cu_{K\alpha}$, $W_{L\alpha}$, $Ta_{L\alpha}$, $Hf_{L\alpha}$, $Ni_{K\beta}$, $Tm_{L\beta}$, $Er_{L\beta}$
Co	$Zn_{K\alpha}$, $W_{L\alpha}$, $Cu_{K\beta}$, $Yb_{L\beta}$, $Lu_{L\beta}$, $Re_{L\alpha}$, $Os_{L\alpha}$
Ni	$Ga_{K\alpha}$, $Pt_{L\alpha}$, $Ir_{L\alpha}$, $Ta_{L\beta}$, $Hf_{L\beta}$
Cu	$Zn_{K\beta}$, $Au_{L\alpha}$, $W_{L\beta}$, $Hg_{L\alpha}$, $Ge_{K\alpha}$

Spurious peaks can also appear by energy doubling if the charge collection induced by the first fluorescence photon is not complete when a second photon from the same fluorescence source impinges. Then, the detector registers twice the number of charges, and a sum-up peak results. Sum-up peaks can be reduced by a pulse pile-up rejector (PUR). Contamination along the beam path, e.g., Fe in the detector window (Be), may also result in spurious peaks and limit the detection capability for certain elements [362].

4.1.4. Quantification

Reliable quantification is based on peak-search software that combines peak localization, peak identification, and element deduction. Element deduction means that, for unambiguous detection, at least two of the principal peaks be detected for each analyte of interest. In trace analysis, only the strongest α peaks can be detected, and special attention must be paid to interfering satellites and spurious peaks.

By using an optically flat plate of a pure element such as Ni, TXRF systems can be calibrated absolutely [363]:

$$I_X = B_X c_X \tag{4.3}$$

where I_X is the background-corrected net intensity of the principal peak of analyte X, B_X a proportionality factor relative to the absolute sensitivity of the standard reference (e.g., an Ni plate), and c_X the concentration of X. Multielement analyses are based on known relative sensitivities S:

$$S_j = \frac{I_j / c_j}{I_{ref} / c_{ref}} S_{ref} \tag{4.4}$$

where the suffix ref denotes reference values. Values of relative sensitivities can be determined by theoretical calculations including, for example, mass absorption [364]. The fluorescence yield is angle-dependent. Because matrix effects are absent in the case of minute sample amounts ($< 1\,\mu g/cm^2$), quantification by internal standardization is possible. Equation (4.4) holds correspondingly.

The bulk-type response curve also depends on surface roughness [365]. Therefore, reference materials must be carefully investigated by angle scan prior to use. Angle-scan characteris-

Figure 101. Block diagram (A) and assembly image (B, also with cap removed) of a silicon drift detector module, including electronics.

tics of the sample, that is, recording the fluorescence intensity at more than one glancing angle near α_{crit}, should not deviate from the reference. The measurement must be carried out under similar optical conditions.

With monochromatic $\mathrm{Au}_{\mathrm{L}\beta}$ (11.44 keV) excitation, the variation of Cu depth distribution in monocrystalline Si with time was studied by means of TXRF [366]. Such and similar effects must be carefully investigated when using reference samples of unknown behavior. Complementary analytical techniques may be helpful. However, the propagation of errors must be taken into consideration; and, moreover, the calibration must cover the concentration range of interest [367] because the accuracy of reference concentrations strongly affects the accuracy of the results [368], [369]. External calibration with reference materials can yield deviations of 3 – 20 % from the true value [370].

However, reliable preparation of controlled spiking has been reported [371]. For general issues of external calibration of TXRF systems, see [372] and [373].

4.1.5. Applications

TXRF is an ideal tool for microanalysis [352], since it has a broad range of linearity (10^{13} – 10^{8} atoms/cm^2) and is extremely surface sensitive and matrix-independent. TXRF can be applied to a great variety of different organic and inorganic samples, such as water, pure chemicals, oils, bodily fluids and tissues, and suspended matter, down to the picogram range.

Figure 102. Fluorescence signal of small particles or thin films deposited on a silicon substrate as sample carrier. The intensity was calculated for particles, thin films, or sections of different thickness but equal mass of the analyte, and plotted against the glancing angle α. A $\mathrm{Mo}_{\mathrm{K}\alpha}$ beam was used for excitation. Particles or films more than 100 nm thick show double intensity below the critical angle of 0.1° [352].

4.1.5.1. Particulate and Film-Type Surface Contamination

The penetration depth of impinging X-rays is very limited under the condition of total reflection. For light substrates such as Si, quartz, and poly(methyl methacrylate), the spectral background of TXRF is six orders of magnitude smaller than that of XRF. The fluorescence signal arises from the uppermost layer; therefore, the scattered intensity, that is, background, is lower than in a conventional XRF arrangement. If metallic smear, organic tissues, or thin (< 100 nm), dried residues of a solution, suspension or dispersion are present on a substrate within the standing wave front, strong oscillation of signal intensity results (Fig. 102). Such oscillations vanish when grain size or film thickness increase to about 1000 nm [374].

One can clearly distinguish thick-film from particulate analytes by means of angle characteristics (cf. curves b and c in Fig. 103). The particulate and thin-layer angle characteristics do not differ at large angles [375], [376]. However, surface roughness crucially modifies peak height [365] and may simulate a stratified structure [377].

Figure 103. Characteristic intensity profiles for three different kinds of concentrations
a) Bulk; b) Particulate; c) Thin-layer
The critical angle α_{crit} is determined by total reflection at the substrate ([352], after [375])

4.1.5.2. Semiconductors

Metrology and contamination analysis in particular have been decisive factors for profitable semiconductor production [378]. Semiconductor applications of TXRF go back to the late 1980s and were introduced by Eichinger et al. [379], [380]. Due to its high sensitivity, wide linear range, facile spectrum deconvolution, and ease of calibration, TXRF has rapidly become the economic workhorse of monitoring cleaning efficiency and front-end wafer cleanliness

Figure 104. Statistical process control chart for TXRF measurement systems. The sensitivity is monitored by daily calibrations with a Ni standard reference sample. When the X-ray intensity sinks below 75 % of the original intensity, the tube must be replaced with a new one.

Figure 105. Limits of detection (3 σ) for VPD-TXRF measurements on 200- and 300-mm Si wafers

[381], [382]. TXRF provides reliable quality-control data that can be easily integrated into the data-management system [383], [384]. Automatic operation with repeated one-point calibration every 8 h, as well as automatic data management and transfer, has led to abundant applications of TXRF (Fig. 104).

Detection limits for various elements by TXRF on Si wafers are shown in Figure 105. Synchrotron radiation (SR) provides a bright and horizontally polarized X-ray excitation that is tightly collimated and diminishes the Compton scattering of silicon. Developments in the field of SR-TXRF and extreme-ultraviolet (EUV) lithography promise improved sensitivity down to the range of less than 10^7 atoms/cm^2 [344], [385–388]. At present, practical applications of SR-TXRF focus on fast mapping of wafers up to a diameter of 300 mm and reference measurement capabilities in the range of $10^5 - 10^7$ atoms/cm^2 [389].

4.1.5.2.1. Depth Profiling by TXRF and Multilayer Structures

Buried layers are important components of microcircuits, and TXRF is a sensitive microanalytical tool for inspection of buried layers

(Fig. 106). On a thick substrate, the angle characteristics is a function of layer thickness. [390], [391]. First-principle calculations have been reported on model-free TXRF of stratified structures [392].

Shallow doping profiles, particularly those of As, require nanoscale information on dopant distribution. Though SIMS can be reliably applied for layers below 5 nm depth, the technique of choice for the upper subsurface is angle-dependent TXRF [393]. Using angle-scan TXRF allows stratified microstructures to be accurately analyzed for element composition, layer thickness, and density (Fig. 107) [372]. A combination of TXRF with layer-by-layer chemical etching provides reproducible results on the stratigraphy of metallic implants [346], [394–396].

Figure 106. Fluorescence intensity from layers buried in a thick substrate. The intensity as a function of the glancing angle was calculated for layers of different thickness but with a constant area density of the analyte. Silicon was assumed as substrate and $Mo_{K\alpha}$ X-rays as primary beam. Total reflection occurs below 0.1°. Without total reflection, the dashed horizontal line would be valid in all cases [352].

4.1.5.2.2. Vapor Phase Decomposition (VPD) and Droplet Collection

Vapor-phase decomposition and collection (see Figs. 108, 109, 110) is a standardized method of silicon wafer surface analysis [342]. The native oxide on wafer surfaces readily reacts with isothermally distilled HF vapor and forms small droplets on the hydrophobic wafer surface at room temperature [397]. These small droplets can be collected with a scanning droplet. The scanned, accumulated droplets finally contain all dissolved contamination in the scanning droplet. It is dried on a concentrated spot (diameter ca. 150 µm) and measured against the blank droplet residue of the scanning solution [398–400]. VPD-TXRF has been carefully evaluated against standardized surface analytical methods. Care must be taken to use reliable reference materials [401–403].

Figure 107. Angular dependence of the fluorescence radiation emitted from a Co-layered Si substrate. The $Co_{K\alpha}$ intensity is plotted semilogarithmically for layers of different thickness (curve parameter in mm). The maxima for the ultrathin Co layers are localized at the critical angle of Si (dashed vertical line). They are shifted to the critical angle of Co (dotted vertical line) if the layer is more than 10 mm thick ([352], after [372]).

The accuracy of VPD-TXRF depends largely on the reliability of the reference material and on the reproducibility of the droplet-drying procedure (Fig. 109) [406], [407]. Mass absorption sets the upper limit of reliable analyses at 10^{14} atoms/cm^2 [408].

VPD-TXRF is also a facile technique of interface analysis [409], [410]. Automated VPD equipment (Fig. 108) improves both the detection limit (upper range of 10^7 atoms/cm^2) and the reliability (by $> 50\,\%$) of the VPD-TXRF

Figure 108. Wafer surface preparation system (WSPS): automated VPD system for wafer diameters from 100 to 300 mm

measurement [345]. Current research focuses on issues of sample holders [411], [412] and light-element detection capability [413–415].

4.2. Glow Discharge Optical Emission Spectroscopy (GD-OES)

Glow discharge optical emission spectroscopy (GD-OES) is becoming one of the most important techniques for the direct analysis of solids at their surface, through their depth and in their bulk. The ease and speed of operation, high sensitivity to all elements, accuracy of analysis, and breadth of application make GD-OES a very versatile and powerful technique. GD-OES has proven its capability, in particular, for the rapid and reliable analysis of metallic coatings, oxide scales, and diffusion and alloy layers, and can thus be used for quality control of technical products during different stages of heat treatment, such as nitriding or nitrocarburizing steps, and for hard coating and PVD processes.

4.2.1. Principles

Glow discharges are low-pressure electrical discharges in a noble gas at pressures of $10^2 - 10^3$ Pa [416]. The glow discharge in the discharge chamber consists of several alternating dark and luminous zones. The complicated structure may be altered by varying the geometry of the chamber, especially the distance between the two electrodes. In general, when the electrode distance is relatively long, the positive column (the bright zone near the anode) is the most prominent of the zones in the discharge. When the space between the electrodes is reduced, the positive column shrinks and finally disappears, while the negative glow (the bright zone near the cathode) and the cathode dark space are hardly affected. Both negative glow and cathode dark space are essential to maintain the discharge and cannot be dispensed with. In this case, the discharge is called an obstructed glow and can be realized when the interelectrode separation is just a few times the thickness of the cathode dark space.

Figure 109. Dried VPD droplets. Left: worst case, the VPD solution exploded under fast drying with an infrared lamp, droplet size of a few mm; Right: best case (WSPS), VPD solution dried under controlled conditions with vacuum and carrier gas [367].

Figure 110. Detection limit of TXRF for the residues of aqueous solutions as a function of the atomic number of the analyte element. Three excitations modes were used: a) W tube; 50 kV; Ni filter, cutoff 35 keV; b) Mo tube; 50 kV; Mo filter, cutoff 20 keV; (c) W tube, 25 kV, Cu filter. The three curves to the left were determined by the detection of K peaks; the three curves to the right, by that of L peaks ([352], after [404], [405]).

Discharge tubes working under obstructed-glow conditions are employed extensively as excitation sources for optical emission spectrometry. For this purpose the analytical sample of interest serves as the cathode. During the discharge, the cathode is bombarded by positive ions formed from the noble gas. This bombardment produces a surface erosion called cathodic sputtering: atoms, electrons, and ions are removed from the surface of the material constituting the cathode. This sputtered material then participates in different phenomena in the discharge. The result is an emission of photons corresponding to the characteristic spectral lines of the elements in the plasma. Thus the glow discharge provides information on the elemental composition of the analytical material being removed layer-by-layer from the cathode. The sputter rates vary from 0.1 nm/s up to more than 100 nm/s, depending on the cathode material and the excitation conditions used. Therefore, the glow discharge provides a rapid and detailed characterization of near-surface layers, interfaces, and bulk composition when the spectral line intensities of the elements of interest are recorded simultaneously.

Figure 111. Diagram of a typical glow discharge device used for GD-OES depth profiling [422]

4.2.2. Instrumentation

Glow Discharge Sources. If the potential applied across the cathode and the anode is constant (dc) then conductive materials can be analyzed; if the potential is varied at radio frequency (rf) then both conductive and nonconductive materials can be analyzed.

The most important dc-discharge source used to date in GD-OES is the *Grimm-type source* [417], the principle of which is illustrated in Figure 111. In the Grimm source the anode is no longer a flat plate but a hollow tube, the annular face of which approaches to within 0.1 – 0.2 mm of the surface of the sample. This restricts the discharge to a sample area equal to the aperture of the anode tube (typically 4 – 8 mm). The sample is mounted against the discharge chamber and acts as cathode. When the discharge current is sufficiently high, in the so-called *abnormal glow regime*, the whole area is covered by the discharge, very efficient cathodic sputtering results, and the material of the sample is easily removed. To maintain the required low pressure, the sample must be vacuum tight and sealed to the discharge chamber by an O-ring. Normally, flat samples with sufficient low surface roughness are used, although samples with other regular shapes (rods or wires) can also be used with special sample holders and a modified front plate of the discharge chamber. The chamber is evacuated, usually by a rotary pump, and flushed continuously by a noble gas (generally argon). The pressure inside the source during sputtering is typically 300 – 1300 Pa. The optical radiation of the excited sample atoms is observed end-on through a window with the required transmittance; MgF_2 is used most commonly as window material.

Other well-known discharge sources include the boosted sources, which use an additional electrode to achieve a secondary discharge, a magnetic field or microwave power to enhance the efficiency of excitation and thus the analytical capabilities, but none of these sources has been applied so far to surface or depth profile analysis.

The more recent Marcus rf source [418] is operated at pressures similar to those of dc discharge sources, but the essential characteristic is the conventional 13.56 MHz radio-frequency power which is applied to the back of the sample by an impedance matching device. For proper operation the sample must be electrically isolated from all metallic parts of the source and ancillary components to reduce rf radiation and conduction losses. In this way the sample no longer acts as cathode, and the second electrode or counterelectrode (corresponding to the anode in the dc device) is no longer a tube, but is represented by the metallic walls of the discharge chamber. The sample area exposed to the discharge is confined by an orifice disk and is much smaller than the counterelectrode, so that most of the drop in rf potential occurs at the sample and no significant sputtering of the counterelectrode occurs.

The most important difference between dc and rf discharge source is the ability of the rf source to sputter both electrically conductive and nonconducting materials. This enables the elemental analysis of insulating samples directly in the solid state.

Continuous discharge and sputtering of the sample are accomplished by the negative dc self-bias voltage, or offset, which is acquired at the surface of the insulator without any applied external dc potential. This phenomenon is explained by the different mobility of positive ions and electrons, which reverse their direction of movement toward the sample with every half-cycle of the bipolar rf potential. The positive charge of the insulator surface during bombardment with ions is readily neutralized and shifted to negative charge by electrons in the next half-cycle, and this results in the observed steady-state negative offset voltage and hence the effective sputtering of the sample by positive ions.

Spectrometer. Apart from the glow discharge source with its associated gas and power supplies, vacuum pumps and controls, the optical emission spectrometer is the most important part of a GD-OES instrument. To make use of the analytical capability of the discharge source, the spectrometer must have a sufficient spectral resolving power and an adequate spectral range. Depending on the application, a commercial spectrometer can cover the wavelength range from 110 to 800 nm, which contains the most sensitive lines of all elements, including those of the light elements (Li, Be, B, C etc.)

and gases (H, O, N, Cl). The high spectral resolution is required to avoid spectral interference with lines of other elements, in particular of the discharge gas argon.

The most widely used spectrometer designs are the Paschen – Runge polychromator configuration for simultaneous spectrometers and the Czerny – Turner monochromator for sequential analyzers. In the Paschen – Runge mount the concave grating focuses the spectral lines of preselected elements onto fixed exit slits, which are positioned on a Rowland circle. Up to 64 elements can be detected simultaneously in this way. In the Czerny – Turner mount quasi-monochromatic radiation is observed at the exit slit. By turning the plane grating around its axis it is possible to scan a spectral range and to profile an emission line, including background radiation and neighboring spectral lines.

Signal Acquisition. The optical radiation passing the exit slit(s) of the spectrometer is recorded by a detector system. The best known detector is still the photomultiplier tube (PMT) which is implemented in most commercial spectrometers. The rapid development in the performance of CCD and similar detection techniques makes this detector system very attractive in the future, especially when combined with the well known Échelle spectrometer. This configuration enables a small-sized spectrometer with high spectral resolving power and high flexibility in line selection.

In the common polychromator system, each detection channel is equipped with a PMT and the corresponding high-voltage supply. Each supply can be adjusted individually to give the appropriate sensitivity for each element required to match the analytical conditions. Due to the linear characteristic of the PMT, the output signal is proportional to the radiation power of the spectral line recorded by each detection channel. The analogue output signals are amplified, converted into digital information and transferred to a PC for further data processing. In case of depth profiling and continuous sample erosion it is necessary to use fast A/D converter, since the acquisition rate must be high (ca. 1 kHz) to ensure a sufficient depth resolution.

4.2.3. Spectral Information

The emission process in a glow discharge source depends on several factors: the number of atoms in the plasma, the availability of energetic particles such as high-energy electrons and metastable argon atoms which provide the excitation energy by numerous collision processes, and the excitation cross sections of the competing energy levels of the elements. It can be estimated that the number of argon atoms in the discharge exceeds the number of sputtered sample atoms by a factor of about 10^3. Since only a small fraction of sputtered atoms is charged and energetically excited, the discharge plasma for a given sample material is dominated mainly by argon atoms. This fact explains why calibration curves obtained with GD-OES are mostly linear over a wide range of elemental concentration. The operating conditions of the discharge, i.e., low pressure and low power input, result in low kinetic temperatures of about 500 – 1000 K and small physical line widths of emission lines. Therefore, the spectral information obtained from the glow discharge source is highly specific and selective. With constant excitation conditions, the spectral line intensities are proportional to the number densities of sputtered atoms in the plasma and hence the element concentration in the sample used. To maintain reproducible excitation conditions in the glow discharge source, the working parameters (e.g., argon pressure, dc current or rf power) are carefully controlled.

4.2.4. Quantification

Due to the complex nature of the discharge conditions, GD-OES is a comparative analytical method, and standard reference materials must be used to establish a unique function relating the measured line intensities and the elemental concentration. In quantitative bulk analysis, which has been developed to very high standards over decades, calibration is carried out with a set of calibration samples of compositions similar to the unknown samples. Normally, a major element is used as reference, and the internal-standard method is applied. This approach is not generally applicable to depth-profile analysis, since the different layers encountered in

a depth profile often represent widely different types of material, which means that a common reference element is not available.

The quantification algorithm most commonly used in dc GD-OES depth profiling is based on the concept of *matrix-independent emission yield* R_{ik} [419]. In this approach the observed line intensity I_{ik} is described by the concentration c_i of element i in the sample j and by the sputtering rate q_j:

$$I_{ik} = c_i q_j R_{ik} \tag{4.5}$$

The sputtered mass δm_i of element i during time increment δt is given by:

$$\delta m_i = I_{ik} \delta t / R_{ik} \tag{4.6}$$

The emission yield R_{ik} is defined as the radiation of the spectral line k of an element i emitted per unit sputtered mass and must be determined independently for each spectral line. The quantities q_j R_{ik} are derived from a variety of different standard bulk samples with different sputtering rates. In practice, both sputtering rates and excitation probability are influenced by the working conditions of the discharge. The systematic variation of discharge voltage U_g and current I leads to the empirical intensity expression [420]:

$$I_{ik} = K_{ik} c_i C_Q I^{A_k} f_k (U_g) \tag{4.7}$$

where K_{ik} is an atom- and instrument-dependent constant characteristic of the spectral line k of element i; A_k is a matrix-independent constant characteristic of the spectral line k; $f_k(U_g)$ is a first- to third-degree polynomial, also characteristic of the spectral line k; and C_Q is a constant related to the probability of a sample atom being ejected during the sputtering process. The emission-yield happroach as proven to be extremely successful for a large and increasing number of applications and has been implemented in commercial GD-OES depth profiling instruments.

4.2.5. Depth Profiling

The primary information obtained in GD-OES depth profile measurements is the relative intensity from the elemental detection channels as a function of sputtering time. The intensity versus time curves obtained for different elements can be converted into concentration versus depth curves by applying Equations (4.5) – (4.7) and the sum normalization of all concentrations to 100 %. The depth is determined from the sputtered mass, that is, the quantity obtained by the emission-yield technique. The density of composite material is calculated by an approach which is based on a weighted average of the density of pure elements. This method gives very accurate results for all types of metal alloys, but tends to be less accurate in the case of compounds which contain light and gaseous elements (oxides, nitrides, carbides, etc.). In general, accuracy, precision, and repeatability of quantitative GD-OES depth-profile analyses are assured on the basis of interlaboratory round-robin tests [421], by layered certified reference materials [422], and by comparison with other surface techniques [423–425].

The information depth achieved by GD technique is determined, in principle, by the depth of penetration of the incident ions, which is in the range of a few nanometers at the relatively low energies employed in the discharge. The practical depth resolution, however, is larger and is determined by several effects which are due to the sputtering process (preferential sputtering, atomic mixing), the sample properties (surface roughness, polycrystalline structure), and most seriously by the nonuniform erosion of the sample material. Most of these effects are also inherent in other techniques using sputtering for surface and depth-profile analysis. In practice, the depth resolution of GD-OES depth profile measurements is roughly proportional to the sputtered depth, and usually deteriorates from the nanometer range obtained at near-surface layers to micrometer range at depths of several micrometers [426], [427]. The lateral resolution of the GD-OES technique, on the other hand, is restricted by the size of the sputtered area of the sample surface (usually 4 – 8 mm in diameter) and is much larger than with other surface techniques. Both lateral and depth resolution of GD-OES are usually adequate, however, for the chemical characterization of technical products.

4.2.6. Applications

In comparison to other surface analytical techniques, GD-OES has the advantage of easy use,

Figure 112. Quantitative depth profile of a TiN – NiP coating on steel [431]

rapid in-depth analysis, wide depth range, and sensitivity, for all elements. Therefore, GD-OES depth profiling is of primary interest for industrial use, especially for quality control of large-scale technical products. The numerous applications cover the field of different coating technologies of metallic surfaces, the investigation of corrosion effects, and reactive diffusion processes in layer – bulk interfaces [428].

In recent years the applications of GD-OES concentrated mainly on steel analysis and the qualitative characterization of surfaces of cold- and hot-rolled steels in order to control enrichment or depletion of minor and trace elements during the manufacturing process or the formation of oxide scales [423], [429]. Zinc-based coatings are of great industrial importance in materials for buildings and for car manufacturing. Because of the wide industrial application of hot-dip galvanizing and electroplating technologies, the rapid and reliable determination of the thickness of the zinc coatings (typically 5 – 30 µm) and the composition of major elements in these layers [420], [430] is a great challenge to surface- and depth-profiling methods. GD-OES has proven its capability in this field (Fig. 112 [431]) and is accepted as a standard method [432]. Other typical applications of GD-OES include the analysis of surface hardened steel after the process of nitriding or carburizing [433], and after different processes of hard coatings, i.e. physical vapor deposition (PVD), of TiN layers [434].

Figure 113. Quantitative depth profile of a commercial pre-painted metal-coated steel sample [435].

Besides the analysis of relatively thick metallic coatings and diffusion profiles, GD-OES is also applied successfully to the analysis of thin protective layers (thickness typically < 100 nm) such as phosphate and chromate layers on steel [420] or surface films on aluminum [435].

The examples given so far represent basic applications of GD-OES depth profile analysis with the dc glow discharge source. The rf source has unsurpassed capability when composite materials such as ceramics, coated glass surfaces, and polymer coatings are analyzed. A quantitative depth profile on pre-painted metal-coated steel is shown as an example in Figure 113 [436].

4.3. Surface-Sensitive IR and Raman Spectroscopy; Ellipsometry

4.3.1. Reflection – Absorption IR Spectroscopy (RAIRS)

Reflection – absorption infrared spectroscopy is a vibrational spectroscopic method that is frequently applied in the research areas of chemical, physical, and biological research [437–440]. The technique is well established for the identification and characterization of chemical state and structure of molecules and thin films adsorbed on metallic and non-metallic surfaces. Vibrational spectra are used as characteristic fingerprints for adsorbate molecules, adsorption configurations, and structures. The method is known under various acronyms: RAIRS, IRAS, FT-IRAS, IRRAS, and ERIRS (see Chap. 1), whereby the different names refer to the same principle of measurement using infrared radiation and a reflection – absorption geometry. This technique involves a single external reflection at a substrate covered by the sample, whereby the molecules of the sample absorb radiation at their vibrational frequencies and corresponding absorption bands occur in the spectrum of the reflected radiation. Substrates are chosen which do not show disturbing absorption bands in the spectral range of interest.

4.3.1.1. Principles

Conventionally, RAIRS has been applied to qualitative and quantitative characterization of adsorbed molecules or films on mirrorlike (metallic) substrates [437]. In the 1990s its applicability for quantitative analysis of adsorbates on nonmetallic surfaces (e.g., semiconductors, glasses [439], and water [441]) has been proven, too. However, the dielectric properties of the substrate and the adsorbate determine the optimum condition under which the RAIRS experiment should be carried out. The excitation of vibrational adsorbate modes on metals is governed by a *surface-selection rule*. The amplitude and phase of the reflected radiation depend on the direction of the electric field vector, which is composed of one component parallel to the reflection plane (p-polarized) and another normal to the reflection plane (s-polarized). Considering Fresnel equations, only the p-polarized radiation shows a significant resulting electromagnetic field near the metal surface for high incident angles of radiation near grazing incidence (at ca. 80°). In contrast; the mean-square electric field of radiation polarized in the surface plane is negligible because of the 180° phase shift after reflection at the metal. Therefore, only vibrations with dipole components perpendicular to the surface can be excited efficiently. With p-polarized radiation and incident angles near grazing incidence an increase in signal intensities by a factor of about 17 can be achieved in comparison to transmission experiments [437].

RAIRS spectra show structures of absorption bands, related to vibrations of the bulk or adsorbed molecules. From reflectance spectra the absorbance is commonly determined by calculation of $-\log(R_s/R_o)$, where R_s is the reflectance from the adsorbate-covered substrate, and R_0 the reflectance from the bare substrate. For thin films with strong dipole oscillators the Berreman effect, which leads to an additional spectral feature in the reflectance, must be considered (see Section 4.3.3). The frequencies, intensities, full widths at half maximum, and lineshapes of bands in the absorption spectrum yield information about adsorption states, chemical environment, ordering effects, and vibrational coupling. For example the structure, orientation, and reaction kinetics of alkoxides on Cu(111) surfaces have been determined [442].

In case of films on nonmetallic substrates (semiconductors, dielectrics) the situation is much more complex. In contrast to metal surfaces, both parallel and perpendicular vibrational components of the adsorbate can be detected. It has been shown that sign and intensity of RAIRS bands strongly depend on the angle of incidence, the polarization of the radiation, and the orientation of vibrational transition moments. Figure 114 shows IR reflection spectra

Figure 114. IR reflection spectra of an ODS monolayer on silicon for s- and p-polarised radiation at different incident angles θ. Symmetric (s), asymmetric (as), in plane (ip) and out-off plane (op) CH_2/CH_3 vibrations are marked [439].

of an octadecylsiloxane (ODS) monolayer on a silicon substrate [439] for s- and p-polarized radiation at different incident angles. Absorption bands are assigned to fundamental symmetric and asymmetric CH stretching vibrations. The spectra show significant changes as a function of radiation incidence angle and direction of polarization. In the case of p-polarization the sign of RAIRS bands changes by crossing the Brewster angle at 73°. In addition the spectra provide information concerning the bonding between adsorbate and substrate. By comparison with calculations of relative intensities of absorption bands [439], an average tilt angle of the hydrocarbon chains of about 10° towards the surface normal was concluded.

4.3.1.2. Instrumentation and Applications

In the IR spectral range Fourier transform (FT) interferometers are generally utilized. In comparison to dispersive spectrometers, FTIR offers higher optical throughput and the multiplex advantage at equivalent high spectral resolutions. In the near-IR region, a tungsten-filament lamp, in the mid-IR region a silicon carbide rod (glowbar), and in the far-IR region a mercury-arc lamp are employed as radiation sources. A special radiation source is a synchrotron, which offers high brilliance over the whole IR region. For example, it was applied for in-situ measurements on the anodic oxidation of copper in aqueous solution [443]. Often RAIRS is used as a complementary method to HREELS (see Section 2.5.2.2), which is also a standard method for investigation of dipole-active vibrations, but has a low spectral resolution (ca. 20 cm^{-1} on semiconductor surfaces).

RAIRS is a nondestructive IR technique and also has especially versatile applications, because it does not require vacuum conditions, which are strictly necessary for electron-

spectroscopic methods. Therefore, RAIRS is in principle applicable to growth processes [444]. By applying a polarization – modulation technique, surfaces in can be investigated a gas phase. Higher surface sensitivity is achieved by modulation of the polarization between s and p. Furthermore, this method allows anisotropic near-surface absorption to be distinguished from the isotropic absorption in a gas phase [445].

RAIRS is routinely applied in the area of chemically modified surfaces. A variety of surface systems in electrochemistry [449], polymers research [438], [450], catalysis [437], [445], self-assembling monolayers [439], [440] and protein adsorption [440], [447] have been investigated.

Figure 115. Experimental and simulated PM- (polarisation-modulated) RAIRS spectra of a single monolayer of PGB (A) and $K(LK)_7$ (B) at the air water interface. The surface tension was 20 mN/m [448].

Besides studies of adsorbates on metal and semiconductor surfaces, considerable interest has been aroused by the structural characterization of monolayers at air – water interfaces [441], [446]. Experiments at the gas – water interface have been carried out in biochemical research on the characterization of membrane proteins [447] and structures of biological molecules [448]. Figure 115 presents experimental and simulated RAIRS spectra of a single monolayer of PGB (poly-γ-benzyl-L-glutamate) and a synthetic peptide $K(LK)_7$ at the air – water interface [448]. In the simulations the different secondary structures of both molecules and anisotropic optic constants were taken into account. The PGB spectra show significant features resulting from amide I, amide II ,and ester bands in an α-helix structure. For $K(LK)_7$ the simulations reveal molecules lying in antiparallel β-sheets on the water surface. The wavenumber of the amide I mode ($1622\,cm^{-1}$) provides information on interactions between the antiparallel β-sheets and the substrate. The knowledge of such optical data is of great interest for determination of the main secondary structures (α-helix, β-sheets) found in proteins and polypeptides [448].

4.3.2. Surface Raman Spectroscopy

4.3.2.1. Principles

Raman scattering [451] is one of the phenomena that occur when electromagnetic radiation interacts with a molecule or a crystal. By the inelastic scattering process, photons lose energy for exciting molecular or lattice vibrations (Stokes scattering) or even gain energy (anti-Stokes scattering) when the transition starts from an excited vibrational state with a final state of lower energy (e.g., ground state). When a sample is irradiated by monochromatic light, the scattered light exhibits a spectrum of wavelengths in which the intensity peaks are shifted from the excitation wavelength by an amount of energy equivalent to that for the excitation of molecular vibration modes or crystal phonons. These vibrational spectra are highly specific for the material studied and can be used for an unambiguous identification of substances.

The Raman cross section of molecules is generally low. Therefore, intense light sources and low-noise detectors must be used, and the high sensitivities required for surface analyses

are difficult to achieve. Another issue in Raman spectroscopy is the superposition of the stronger fluorescence of the substances or their impurities on the weak Raman spectrum. This problem can be overcome by the use of longer excitation wavelengths, which cannot excite electronic transitions. This concept works well for numerous samples. However, near-infrared excitation wavelengths result in lower sensitivity in comparison with visible excitation because of the noise of detectors working in this range.

Raman spectroscopy does not need vacuum and is, in principle, applicable to all optically accessible samples. Even inclusions in glasses or minerals, substances in aqueous solutions, or substances packaged in transparent glass or plastics can be analyzed. Small particles down to 1 μm can also be characterized by proper focusing of the exciting laser beam.

4.3.2.2. Surface-Enhanced Raman Scattering (SERS)

The application of Raman spectroscopy in surface analysis is limited by the low scattering cross section of the molecules and the correspondingly low intensities of their Raman bands. This situation can be clearly improved by surface-enhanced Raman scattering (SERS) [452], [453]: The Raman scattering of molecules adsorbed on rough metal surfaces or small metal particles (Fig. 116) can be increased by six or even more orders of magnitude by electromagnetic and chemical effects. This large enhancement enables easy analysis of molecular monolayers on appropriate surfaces. Even 1 % of a monolayer has been observed, and the detection of single molecules on optimum metal particles has been reported [454].

The first SERS experiments were performed with electrochemically roughened electrodes and metal colloids. Meanwhile, numerous further types of suitable SERS substrates are known; for example, metal island films, metal films over nanoparticles or rough substrates, gratings, and sputter-deposited metal particles. Colloidal and sputtered particles can be deposited on many different materials, thus making SERS a widely applicable method.

Figure 116. Scheme of an SERS-active substrate and the measuring arrangement. Alumina nanoparticles are deposited on a glass surface and produce the required roughness. A thin silver layer is evaporated onto the nanoparticles and serves for enhancement. Organic molecules adsorbed on the silver surface can be detected by irradiation with a laser and collecting the Raman-scattered light.

4.3.2.2.1. Instrumentation

The scattering effect was first observed by C. V. Raman in 1928 by using sunlight and complementary filters [451]. Later mercury vapor lamps were used for illumination of samples. Current Raman spectrometers use lasers as monochromatic light sources. Different types of lasers can be used, depending on the required wavelength, sensitivity, and spectral resolution. Gas lasers such as Ar^+ and HeNe lasers are commonly used because of their narrow, well-defined spectral lines, stability, and beam quality. High intensity Ar^+ lasers require high maintenance costs and consume a lot of electrical power and cooling water. Diode lasers are more convenient. Powerful diode lasers for Raman spectroscopy generally emit red wavelengths which are suitable for avoiding fluorescence and fit to the sensitivity range of silicon detectors. Diode lasers must be frequency-stabilized since their emission frequency is not defined by narrow transitions. Furthermore, spontaneous emission background and low-intensity sidebands must be filtered out when applying diode lasers for high-sensitivity Raman measurements. Solid-state lasers emitting in the near-infrared such as Nd:YAG lasers are used in combination with Fourier transform spectrometers.

Sample optics focus the laser onto the sample and collect the Raman-scattered light. In the widespread backscattering or 180° arrangement, a single objective serves to both focus the laser

and collect the scattered light. This makes measurements easy, since only the distance between sample and objective need be adjusted. Transparency of the whole sample is not needed with a backscattering arrangement. Therefore, Raman spectroscopy is well suited for in situ measurements at interfaces between gases, liquids, and solids with at least one transparent phase.

Elastically scattered laser light must be removed in front of the spectrograph because it is several orders of magnitude more intense than the Raman-scattered radiation and would otherwise produce stray radiation at the detector. Nowadays, holographic notch filters are mostly used for this purpose because of their high transmission of desired and strong suppression of undesired wavelengths. Premonochromators are preferable for measurements at low wavenumbers and for varying laser wavelengths.

The spectral analysis of the Raman-scattered light is performed by dispersive or Fourier transform (FT) spectrometers. Dispersive spectrometers decompose the radiation according to its wavelength by a grating monochromator. FT spectrometers calculate the spectrum from an interference pattern (interferogram) produced by an interferometer with a variable path length within one of the interferometer arms. Monochromators are preferable in the visible spectral range. Compact and robust monochromators without moving parts can be used in rough environments, whereas larger high-resolution devices are mainly used in research. In combination with array detectors, imaging monochromators can use the multichannel advantage and thus produce large signal-to-noise (S/N) ratios during short measuring times. FT spectrometers also produce considerable S/N ratios by virtue of their throughput advantage. However, the noise of their near-IR detectors is considerably larger than that of detectors operating in the visible region. The main advantages of FT spectrometers are strong suppression of fluorescence by using long wavelength excitation and variable spectral resolution.

Charge-coupled device (CCD) detectors are preferred in the visible spectral range because of their low dark current, high quantum efficiency, and the multichannel capability. They must be cooled thermoelectrically or by liquid nitrogen for high-sensitivity applications such as surface spectroscopy. The sensitivity of CCD detectors decreases considerably for wavelengths larger than 1 μm due to the band gap of the silicon material. Therefore, other semiconductor detectors with larger dark currents, such as germanium or InGaAs, must be used for near-IR Raman spectroscopy.

Different accessories are available for Raman spectroscopy. Confocal microscopes provide a lateral resolution of about 1 μm and a depth resolution down to about 2 μm. The depth resolution is especially important for surface and interface spectroscopy since it helps to eliminate Raman signals from the bulk phases. Fiber optics can be used for guiding the exciting laser light to the sample and the Raman-scattered light to the spectrometer, thus making sample changing easier and avoiding hazards due to freely propagating laser light. Special sample cells were constructed for measurements at high or low temperatures, high pressures, and for laser multipass through gaseous samples.

4.3.2.2.2. Spectral Information

At least for large molecules, Raman spectra show numerous bands which cannot always completely be assigned to certain vibrational modes. However, the many bands, when measured with appropriate spectral resolution, can serve for an unambiguous identification of substances by comparing the spectral pattern (fingerprint) to those of references if suitable reference spectra are available.

Several bands in characteristic spectral regions can be definitely assigned to molecular or crystal vibrations, especially if some information on the chemical composition of the sample is available. For instance, these bands allow the identification of aromatic or aliphatic hydrogen atoms, carbonyls, thiols, double or triple bonds, heterocycles, and other groups or skeletal components. Vibrations of weakly polar and even symmetrically bonded atoms generally result in intense Raman bands because Raman activity is connected with changes in the molecular polarizability during the vibration. This is a major difference to IR spectroscopy, where bands from vibrations causing changes in the dipole moment dominate the spectrum. Raman bands of carbon – carbon bonds are readily observable.

Strong vibrational coupling along carbon chains and symmetry selection rules make these bands sensitive markers for substitution at aromatic rings and the conformation of the carbon backbone. Structural isomers usually possess very different spectra and can therefore be easily distinguished.

Polarization effects are an additional feature of Raman spectroscopy that improves the assignment of bands and allows the determination of molecular orientations. For isotropic phases, the analysis of polarized and nonpolarized bands allows the determination of the symmetry of the respective vibrations. For aligned molecules in crystals or at surfaces, up to six independent Raman spectra can be measured in dependence on polarization and propagation direction of incident and scattered light with respect to the molecular or crystal axes.

4.3.2.2.3. Applications

Developments in Raman equipment have led to a considerable increase in sensitivity. This allowed reactions of organic monolayers at carbon surfaces to be monitored [455] and the structure of Langmuir – Blodgett monolayers to be analyzed without any enhancement effects. This unenhanced surface Raman spectroscopy is expected to be applied to various technically or scientifically important surfaces and interfaces. Nevertheless, it requires a careful optimization of the apparatus, data treatment, and sample preparation. The surfaces of porous materials such as catalysts, molecular sieves, and adsorbents are much more readily accessible to Raman spectroscopy, since larger amounts of adsorbed substance can be placed within the laser focus, thus contributing to the scattering process.

SERS exhibits excellent sensitivity but is restricted to specially prepared "active" surfaces. Silver, gold, and copper electrodes are easily activated by roughening with reduction – oxidation cycles. Therefore, SERS was broadly applied in electrochemistry for monitoring adsorption, orientation, and reactions of molecules on these electrodes in situ. Further electrode and catalyst materials are accessible to SERS by deposition of such thin layers on SERS-active silver supports.

Coating of metal SERS substrates with organic receptor layers makes SERS promising for highly sensitive chemo-optical sensors for organic trace analysis in water and air [456]. The combination of selective adsorption with the measurement of the molecule-specific SERS spectra can reduce cross-sensitivities considerably. SERS substrates with bare metal surfaces irreversibly adsorb thioorganics (Fig. 117) and other compounds and they thus can serve for the detection and identification of very low gas or solution concentrations of these substances [457].

SERS was also applied as sensitive, molecule-specific detection method in chromatography, e.g. thin layer, liquid and gas chromatography.

Figure 117. Raman spectrum of methyl mercaptan (a) and SERS spectrum of methyl mercaptide (b) formed by adsorption of the mercaptan on a silver surface. The surface reaction is proven by the disappearance of the S–H stretching and bending bands at 2575 and 806 cm^{-1}, respectively. The Raman shift of the C–S stretching band around 700 cm^{-1} is decreased during adsorption by withdrawal of electron density from the C–S bond due to bonding to the silver. The symmetric methyl stretching band appears above 2900 cm^{-1} [457].

4.3.2.3. Nonlinear Optical Spectroscopy

Unlike linear optical effects such as absorption, reflection, and scattering, second-order nonlinear optical effects are inherently specific for surfaces and interfaces. These effects, namely, second harmonic generation (SHG) and sum frequency generation (SFG), are dipole forbidden in the bulk of centrosymmetric media. Especially in the investigation of isotropic phases such as liquids, gases, and amorphous solids,

signals arise exclusively from the surface or interface region, where broken symmetry is found. Nonlinear optics are applicable in situ without the need for vacuum, and in addition they show a fast time response.

Surface SHG [458] produces frequency-doubled radiation from a single pulsed laser beam. Intensity, polarization dependence, and rotational anisotropy of the SHG provide information on the surface concentration and orientation of adsorbed molecules, as well as on the symmetry of surface structures. SHG was successfully applied for the analysis of adsorption kinetics and ordering effects on surfaces and interfaces, reconstruction of solid surfaces and other surface phase transitions, as well as potential-induced phenomena on electrode surfaces.

SFG [459], [460] uses two different laser frequencies for the generation of the sum frequency. Tuning one laser in the infrared spectral range allows molecular vibrations of adsorbed molecules to be monitored. SFG includes the capabilities of SHG and can, in addition, identify molecules and their structure on the surface by analyzing the vibration modes. It has been applied to the observation of surfactants at liquid surfaces and interfaces, as well as the ordering of interfacial water molecules.

4.3.3. UV – VIS – IR Ellipsometry (ELL)

4.3.3.1. Principles

Ellipsometry is a method of measuring film thickness, refractive index, and extinction coefficient of single films, layer stacks, and substrate materials to very high sensitivity. Rough surfaces, interfaces, material gradients, as well as mixtures of different materials can be analyzed.

Film thicknesses between 0.1 nm and 100 µm can be measured, depending on the spectral range used for the analysis and the homogeneity of the thicker films. Thicknesses smaller than 1 µm can be determined with a sensitivity better than 0.01 nm. Thicknesses in the micrometer range can be analyzed with a sensitivity typically better than 1 nm.

The refractive index of a film or a substrate material can be measured with a sensitivity better than 5×10^{-4}, which is the highest available value for noninvasive optical measuring methods, especially for thin films. The extinction coefficient can be measured with nearly the same sensitivity, which corresponds to a lower limit of $10 - 100\,\mathrm{cm}^{-1}$ for the absorption coefficient of the material.

The number of measurable layers of a stack is only limited by the optical contrast between the different layers. In practice, stacks of ten layers and more can be analyzed by ellipsometry. Further advantages of ellipsometry compared to other metrological methods are the noninvasive and nondestructive character of the optical method, the low energy input into the sample, the direct measurement of the dielectric function of materials, and the ability to take measurements in any kind of optically transparent environment.

The principal of measurement is shown schematically in Figure 118. Linear polarized light is reflected from a sample surface, which must be flat and sufficiently reflecting. The polarization state of the incident light is changed by the reflection into elliptically polarized light. The parameters measured by ellipsometry are $\tan\Psi$, the amplitude ratio of the resolved components of the electric field vector of the reflected light parallel to and perpendicular to the plane of incidence, and $\cos\Delta$, the phase difference of the two components. An unambiguous determination of the phase angle Δ in the whole data range between 0 and 360° is possible by using a retarder to give circularly polarized light as incident light in a second measurement in which the parameters $\tan\Psi$ and $\sin\Delta$ are determined.

Figure 118. Principle of ellipsometry measurements

The information about the properties of the sample are contained in the complex ratio ρ of the Fresnel reflection coefficients parallel to (r_p) and perpendicular to (r_s) the incident plane-polarized electric field vector:

$$r = \frac{r_p}{r_s} \tag{4.8}$$

The fundamental equation of ellipsometry [461]

$$r = \tan\Psi \cdot e^{i\Delta} \tag{4.9}$$

describes the connection between the measured quantities Ψ, Δ and the sample properties contained in the reflection coefficients, and hence in ρ. In principal this complex equation can be solved analytically only for pure substrates. Each more complex structure requires an optical modeling of the sample and a fit of the calculated ratio ρ to the measured quantities Ψ and Δ. Ψ and Δ are always correct quantities provided the ellipsometer is working correctly. Film thickness, refractive index, extinction coefficient, and other parameters are calculated on the basis of a model. The choice of a correct optical model of the sample is a fundamental assumption for correct values of all calculated parameters.

The thickness of a film influences the interference of light waves reflected from the front and back side of the film, and hence the reflectance. Therefore, the thickness of an absorbing film can only be measured as long as there is still a contribution of back-side reflection to the reflectance of the sample. Typical measurable thicknesses of metallic layers are less than 50 nm.

Ellipsometric measurements depend on the incident angle ϕ due to the angle dependence of the reflection coefficients r_s and r_p. Large differences between both quantities are found for angles above 50°, whereby r_p has a local minimum at the so-called Brewster angle. This angle is between 50 and 60° for transparent materials and greater than 70° for most absorbing materials. Ellipsometric measurements close to the Brewster angle of the substrate are especially sensitive for very thin layers on top of the substrate. Multiple-angle measurements are suitable for confirming optical models of a sample structure.

Two measured ellipsometric angles Ψ and Δ at a fixed wavelength and a fixed incident angle allow the calculation of at most two other parameters, for example, film thickness and refractive index of a transparent layer. Multiple-angle measurements increase the number of measured quantities and hence the number of parameters which can be determined for a specific sample. But in this case, too, the number of measurable parameters will typically not larger than four or five. Wavelength-dependent ellipsometric measurements (spectroscopic ellipsometry) further increase the number of measurable parameters, and hence the complexity of the analyzable sample structure. Spectroscopic ellipsometry allows the calculation of the dispersion of the refractive index and the extinction coefficient of materials, as well as the analysis more complex sample structures (e.g. multilayer stacks, interfaces, material gradients, material compositions) on the basis of parameterized dielectric functions which drastically reduce the number of unknown parameters compared to the number of measured ellipsometric angles.

Spectroscopic ellipsometry is sensitive to the dielectric functions of the different materials used in a layer stack. But it is not a compositional analytical technique. The combination with one of the compositional techniques such as AES or XPS and with XTEM for information about the vertical structure can provide valuable additional information for creating a suitable optical model of an unknown complex sample structure.

4.3.3.2. Instrumentation

The basic configuration of an ellipsometer is very simple: light source – polarizer – sample – polarizer – detector. Advanced configurations use a phase shift device (retarder) before or after the sample.

There are manys in which a specific ellipsometer can be realized. The main differences consist in the way in which the light is polarized and the detection of the polarization state of the reflected light. The light source can be monochromatic (lasers), white light (Xe arc lamp, deuterium lamp, halogen lamp) with a monochromator, or silicon carbide rods (glowbars; mainly for IR ellipsometry).

Photomultiplier tubes (vacuum UV), Si photodiodes (UV – VIS), Ge or InGaAs photodiodes (NIR), and MCT (HgCdTe) or DTGS detectors (MIR) are used as broadband detectors. They must be operated with a monochromator if a white-light source is used. Fast spectroscopic ellipsometers use photometers and diode arrays as detectors. This allows simultaneous detection of

multiple wavelengths rather than sequential detection. State-of-the-art ellipsometry in the IR spectral region (ca. 0.8 – 100 µm wavelength) uses modulated white light from an FT-IR instrument and broadband detectors to measure the reflected light. Intensity spectra are generated by Fourier transformation of the detected signal. Ellipsometric measurements are performed at a fixed angle of incidence. Each ellipsometer configuration can be operated in a discrete-wavelength or spectroscopic, that is, variable angle of incidence mode.

Null ellipsometers are one of the oldest configurations, in which a revolving polarizer and a revolving compensator are used to change the polarization state of the incident light, and a revolving polarizer (analyzer) is used to analyze the reflected light. The angular position of the optical elements is changed until the light intensity on the detector is zero. This configuration is one of the most accurate but also the slowest, even if automated.

Rotating-element ellipsometers have a continuously rotating element (10 – 40 Hz frequency of revolution), which allows automated acquisition and faster measurement. Most of the instruments used nowadays have this configuration. Polarizer (rotating polarizer ellipsometer, RPE) or analyzer (rotating analyzer ellipsometer, RAE) can be used as rotating element. The detector signal is measured as function of time and is then Fourier analyzed to obtain the ellipsometric angles Ψ and Δ. The RPE configuration has the advantage that any polarization sensitivity of the detector (photomultiplier tube, monochromator) does not influence the measurement. The polarization state of the detected light is fixed by the fixed analyzer position. The disadvantage is the sensitivity to residual polarized light of the light beam incident on the rotating polarizer. The RAE configuration has the advantage of being insensitive to any residual polarization of the light source (laser, white-light source with monochromator), but errors can occur due to polarization sensitivity of the detector (photomultiplier tube). With polarization-insensitive Si photodiodes as detectors, this configuration is most often used for discrete wavelength ellipsometers. Typically, single-wavelength ellipsometers are equipped with a quarter-wave plate (compensator) which can be moved into the light beam. The linear polarized light is changed into circularly polarized (in general, elliptically polarized) light after passing through the quarter-wave plate. Thereby, the measured ellipsometric angle Δ is shifted by 90°, and it can be determined over the whole data range of 0 to 360°, and the large uncertainty in Δ when its value is close to 0 or 180° is removed.

Spectroscopic ellipsometers that measure Δ over the whole data range require an achromatic compensator with a phase shift close to 90° over a large spectral range. The compensator can be located between polarizer and sample, or between sample and analyzer.

Step-scan polarizer/analyzer (SSP/SSA) and continuously rotating element configurations are used for diode-array or FT-IR-based ellipsometers. In the SSP or SSA modus, complete intensity spectra are measured at a number of angle positions of the revolving polarizer/analyzer. The acquisition time varies between some seconds (UV – VIS) and several minutes (IR), depending on the intensity of the incident beam and the reflectance of the sample. The measurements are fast compared to the monochromator-based configurations and very accurate regarding the exact positioning of the revolving element. The continuously rotating element configuration is used for very fast spectroscopic ellipsometers measuring complete ellipsometric spectra in less than 100 ms. For such instruments, the intensity at each wavelength (pixel of the diode array) is accumulated over a 45° revolution angle of the rotating element.

A few instruments have a continuously rotating compensator and fixed polarizer and analyzer. The advantage of this configuration is the insensitivity to residual polarization of the light source or a polarization sensitivity of the detector. The disadvantage is the large influence of a small misalignment of the rotating achromatic compensator on the performance of the instrument.

Polarization modulation ellipsometers use a photo-elastic modulator to modulate the polarization state of the incident beam. Polarizer and analyzer are fixed during the measurement. A Fourier analysis of the time-dependent signal gives the ellipsometric parameters Ψ and Δ. The advantages of this configuration is the very high measuring speed (typical modulation frequency of 50 kHz) for discrete wavelengths and the lack of moving parts. The ellipsometric angle Δ can

be measured over the whole range of 0° to 360°. Disadvantages are the frequent calibration of the instrument owing to the high temperature dependence of the polarization modulator and the limited measurement speed for complete spectra.

The infrared ellipsometer consists of a combination of a Fourier transform spectrometer (FTS) and a photometric ellipsometer. One of the two polarizers (the analyzer) is moved step by step in four or more azimuths, because the spectrum must be constant during the scan of the FTS. From these spectra, the $\tan\Psi$ and $\cos\Delta$ spectra are calculated. In this case, only Δ is determined in the range of 0 – 180° with a strongly reduced accuracy in the neighborhood of 0 and 180°. This problem can be overcome by using a retarder (compensator) with a phase shift of approximately 90° in a second measurement. Thereby, $\cos\Delta$ and $\sin\Delta$ are measured independently with full Δ information [465].

In a second kind of IR ellipsometer, a photoelastic modulator (PEM) as a dynamic retarder replaces the static one. The PEM produces a sinusoidal phase shift of approximately 40 kHz and supplies the detector exit with signals of the ground frequency and the second harmonic. From these two frequencies and two settings of the polarizer and PEM the ellipsometric spectra are determined [466]. This ellipsometer system is mainly used for fast and relative measurements.

4.3.3.3. Applications

UV – VIS – NIR Spectral Region. Spectroscopic ellipsometry in the UV – VIS – NIR region is mainly used for the characterization of new materials (e.g., photoresists, polymers, low-*k* dielectrics, semiconductors, composite materials), the analysis of multilayer stacks (e.g., low-*k* and antireflection (AR) layer stacks on architectural glass, flat-panel applications, silicon IC technology, optoelectronic devices, photonic devices), the qualification of a large number of deposition processes for production and R&D applications, as well as in-situ monitoring of growth and deposition processes. Spectral range and speed of the measurement are key features which recommend the use of spectroscopic ellipsometers for R&D and production surveillance. The existence of spectroscopic ellipsometers in the spectral range of 140 nm to 2.3 µm allows for many applications in metrology.

Ellipsometry in the vacuum-UV (< 190 nm) allows the analysis of materials for next-generation lithography (photoresists, AR coatings) at the latest exposure wavelengths (157 nm and 193 nm). The short wavelengths increase the sensitivity of ellipsometric measurements of ultrathin films (< 10 nm). New prospects are expected for the analysis of thin metallic and dielectric layers.

In the UV most of the interesting materials like Si, polysilicon, SiGe, GaAs, and other semiconductor materials are strongly absorbent; this permits surface-sensitive measurements. Surface roughness, native oxide covering, material composition, and structural properties can be analyzed.

The VIS – NIR spectral range is mainly used to measure the thickness of single films and layer stacks. Many materials (dielectrics, semiconductors, polymers) are transparent in this spectral range. The analysis of complex layer stacks often requires the knowledge of the dielectric function of each material in the stack or parametrized dispersion models to reduce the number of unknown parameters. The Cauchy formula is often used for transparent layers, the Drude – Lorentz formula works well for metals and IR-active materials, the LENG formula [462] can be used for semiconductor materials, and the Tauc – Lorentz formula [463] works best for amorphous materials. The general Gaussian-broadened polynomial superposition (GBPS) parametric dispersion model [464] can be broadly applied to most materials, including crystalline and amorphous semiconductors, metals, and organics. Figure 119 shows measured ellipsometric spectra of an a-Si/Si_xN_y multilayer deposited on GaAs. Four layers of Si_xN_y and three layers of a-Si were alternately deposited. The dispersion of each layer material was measured on single films. Film thicknesses of 78 nm for a-Si and 145 nm for Si_xN_y were determined for the different layers of the stack by using appropriate parametrized dispersion models for each material. Other typical multilayer applications are dielectric stacks on silicon, spectral selective mirror stacks, and Bragg reflectors for laser devices.

Figure 119. Measured ellipsometric spectra of an a-Si/SiN multilayer stack (7 layers) on GaAs.

Figure 120. Measured and calculated ellipsometric spectra of a 2.5 µm thick SiO_2 layer on Si

Ellipsometric measurements in the NIR are often used for the determination of thickness and refractive index of thicker dielectric films and semiconductor stacks based on InP and GaAs, which are transparent in this spectral region. The wavelength and film thickness should not differ much, so that a highly sensitive ellipsometric measurement of film thickness and refractive index is obtained. Figure 120 shows ellipsometric spectra of an 2.5 µm thick SiO_2 layer on silicon measured between 350 nm and 2.3 µm wavelength. The higher sensitivity in the NIR spectral range is clear. The growing number of applications of 1.55-µm semiconductor lasers forces the application of NIR ellipsometers to control and to monitor AR coatings on laser facets.

Laterally inhomogeneous films and patterned structures of microelectronic and optoelectronic applications require small measuring spots. Measurements in 50×50 µm areas are standard for microspot spectroscopic ellipsometers used in fabrication lines. Areas more than ten times smaller can be analyzed by using discrete-wavelength ellipsometers equipped with laser light sources.

Figure 121. Bulk n, k spectrum of polycarbonate (A) and transmission T spectrum (B) calculated from n, k for a thickness of 1 µm

Infrared Ellipsometry. Infrared ellipsometry typically is carried out in the MIR range of 400 to 5000 cm^{-1}, but also in the NIR and FIR. The resonances of the molecule vibrations or phonons in the solid states provide typical features in the tan Ψ and Δ spectra in the form of relative minima or maxima and dispersionlike structures. For an isotropic bulk, the calculation

of the optical constants – refractive index n and extinction index k is straightforward. In all other cases (thin films and anisotropic materials) iteration procedures are applied. In ellipsometry only angles are measured, and therefore the results are absolute values without using any standard.

Two types of resonances have to be distinguished in the infrared: the strong and the weak oscillator. The strong oscillator is characterized by a region in which the refractive index is lower than unity for wavenumbers higher than the oscillator frequency and is mostly found in inorganic compounds with reststrahlen bands (n, k spectrum of quartz glass, Fig. 124). The weak oscillators always have a refractive index greater than one and are typical of organic compounds (Fig. 121, top). The optical constants of these spectra are calculated by using relations of the metal optics [467]. From the determined ellipsometric optical constants, other experimental configurations can be calculated. In Figure 121 (bottom) the calculated transmission spectrum of the spectra in Figure 121 (top) is shown, which now is suitable for the direct comparison with library spectra.

The spectra of a strong oscillator have some special features which differ from those of a metallic or a dielectric substrate. Different structures in tan Ψ and Δ are observed on a metallic substrate, dependent on the thickness of the film (Fig. 122). For a very thin film up to approximately 100 nm, the Berreman effect is found near the position of $n = k$ and $n < 1$ with a shift to higher wavenumbers relative to the oscillator frequency. This effect decreases with increasing thickness ($d >$ ca. 100 nm) and is replaced by the excitation of a surface wave at the boundary of the dielectric film and metal. Now the oscillator frequency (TO mode) can also be observed. On metallic substrates for thin films ($d <$ ca. 2 µm) only the z component of the electric field is relevant. Thin films on a dielectric substrate always show the oscillator frequency and the Berreman effect simultaneously, because in this case all three components of the electric field are possible (Fig. 123). The relative slope of tan Ψ (max. or min.), Δ, and reflectivity for the parallel component depends on the relative position with respect to the Brewster angle (greater or lower). Greater thickness of the films on both types of substrates leads to dominant interferences.

Double and buried layers can be detected well by infrared ellipsometry if the film material is characterized by reststrahlen bands. The response is observed at the position of the Berreman effect (Fig. 124 with SiO_2, Si_3N_4 layer, and the SiO_2 spectrum for comparison) and also by the TO mode for greater thickness. The thinnest film was observed for the H-terminated silicon surface with a thickness of 0.2 nm [468].

Figure 122. Different spectral features of tan Ψ for a strong model oscillator at 1000 cm^{-1} on a metal substrate. The TO mode (1000 cm^{-1}), Berreman effect (1050 cm^{-1}), and excitation of a surface wave (1090 cm^{-1}) are seen for different thickness: (a) 1, (b) 5, (c) 10, (d) 50, (e) 100, (f) 500, and (g) 1000 nm

Figure 123. Tan Ψ spectra for the same oscillator as in Fig. 122 for a silicon substrate, thicknesses: (a) 1, (b) 5, (c) 10, (d) 50, and (e) 100 nm.

The determination of the optical constants and the thickness is complicated by the problem of calculating three results from two ellipsometric values. This problem can be solved by the oscillator fit in a suitable wavenumber range or

Figure 124. Tan Ψ and Δ spectrum of a double layer of SiO_2 (6 nm) and Si_3N_4 (4 nm) on a silicon substrate (top) and SiO_2 spectrum (bottom) for comparison.

by exploiting the fact that in the infrared ranges without any absorption always exist. In this case the thickness and the refractive index outside of the resonances can be determined for instance by the algorithm of Reinberg [467].

In general it is possible to investigate very thin films up to the subnanometer region by infrared wavelengths which are much greater than the thickness of the film with a ratio of 1:10 000, because of the interference optics of the strong oscillator (Berreman effect).

4.4. Other Photon-Detecting Techniques

4.4.1. Appearance-Potential Methods

Appearance-potential methods all depend on detecting the threshold for ionization of a shallow core level and the fine structure near the threshold, differing only in the way in which detection is performed. In all of them the primary electron energy is ramped upward from near zero to whatever is appropriate to the sample material, while the primary current to the sample is kept constant. As the incident energy is increased, it passes through successive thresholds for the ionization of core levels of atoms in the surface. An ionized core level, as discussed earlier, can recombine by the emission either of a characteristic X-ray photon or of an Auger electron.

4.4.1.1. Soft X-Ray Appearance-Potential Spectroscopy (SXAPS)

In SXAPS the X-ray photons emitted by the sample are detected, normally by letting them strike a photosensitive surface from which photoelectrons are collected, but also – with the advent of X-ray detectors of increased sensitivity – by direct detection. Above the X-ray emission threshold from a particular core level the excitation probability is a function of the densities of unoccupied electronic states. Since two electrons

are involved – the incident and the excited – the shape of the spectral structure is proportional to the self-convolution of the unoccupied state densities.

4.4.1.2. Disappearance-Potential Spectroscopy (DAPS)

Crossing an ionization threshold means that electrons are lost from the primary beam as a result of ionization of a core hole. Thus, if the reflected current of electrons at the primary energy, more usually termed the elastically reflected current, is monitored as a function of energy, it should show a sharp decrease as a threshold is crossed. This is the principle of operation of DAPS. It is in a sense the inverse of AEAPS, and indeed if spectra from the two techniques from the same surface are compared, they can be seen to be mirror images of each other. Background problems occur also in DAPS. The principal advantages of AEAPS and DAPS over SXAPS is that they can be operated at much lower primary electron currents, thus causing less disturbance to any adsorbed species.

4.4.2. Inverse Photoemission Spectroscopy (IPES) and Bremsstrahlung Isochromat Spectroscopy (BIS)

Irradiation of a surface with electrons leads to the emission not only of X-ray photons of energies characteristic of the material, but also of a continuous background of photons called *bremsstrahlung radiation.* If a detector is set to detect only background photons of a particular energy, and the primary electron energy is ramped upward from zero, then the variations in photon flux should mirror the variations in the densities of unoccupied electron states. The process is called inverse photoemission because it is clearly the opposite of ordinary photoemission as in XPS and UPS. Although the name *inverse photoemission spectroscopy* (IPES) should apply to all forms of the inverse photoemission technique, in fact it is confined by usage to the form in which the energy at which the photons are detected is in the UV region, typically with $h\nu = 9.7$ eV. If, on the other hand, a crystal monochromator normally used to provide monochromatized X-rays for XPS is used in reverse, with a detector placed where the electron source is in Figure 3, then detection is at the X-ray energy $h\nu = 1486.6$ eV, and the technique is called *bremsstrahlung isochromat spectroscopy* (BIS).

Since IPES maps the densities of unoccupied states, it is related to other techniques that do the same (i.e., STS and SXAPS). When used in conjunction with a technique that maps the densities of occupied surface states, such as UPS or ELS, a continuous spectrum of state density from occupied to unoccupied can be obtained. Just as in UPS, in which angular resolution allows elucidation of the three-dimensional occupied band structure, so in IPES angular resolution allows mapping of the three-dimensional unoccupied band structure. This version is called *KRIPES* (i.e., K-resolved IPES).

4.4.3. Ion-Beam Spectrochemical Analysis (IBSCA)

Ion irradiation of a surface produces visible-light photons as well as many other types of particle. The light emission arises from the deexcitation of ions and excited neutrals, and is characterized by a spectrum consisting of a series of sharp lines at wavelengths associated with the type of ionized or excited atom. Spectral analysis thus provides elemental identification by reference to standard emission wavelength tables. The technique is called *ion-beam spectrochemical analysis* (IBSCA) but has several other names as well. Typical operating conditions include bombardment by Ar^+ ions at energies in the range 2 – 20 keV, with current densities of 10 – 100 $\mu A/cm^2$; the light emitted just above the target surface is then focused onto the entrance slit of a scanning optical monochromator, which analyzes the light spectrum. Spatial resolution depends on the type of ion source being used, and can be on the order of 2 – 5 μm with a suitable type such as a duoplasmatron. Because emission takes place from-particles ejected from the surface layer, the surface specificity is similar to that of SSIMS (i.e., one atom layer). Quantification can in principle be carried out theoretically but is normally performed by relative intensity measurements, that is, by measuring the intensity of emission from a pure elemental standard under

the same instrumental conditions of analysis as used for an unknown.

5. Scanning Probe Microscopy

The invention of the scanning tunneling microscope (STM) by Binnig and Rohrer in 1981 [470], [471], has triggered a tremendous development of scanning probe microscopy (SPM) techniques [472]. The basic principle all scanning probe microscopes have in common is shown in Figure 125. A sharp probe (e.g., tip, optical fiber, pipette) is rastered across a sample surface by means of piezoelectric translators, while a certain signal is recorded by the probe for each single image point. Because the size of the probe's apex and the distance between the probe and sample surface can be smaller than the wavelength of the analytical signal (e.g., electrons, electromagnetic radiation) information can be obtained in the so-called near-field and thus the resolution is no longer diffraction-limited as given by the wavelength of the signal. Since the measured signal constitutes local information on the surface below the probe, the term local-probe technique is frequently used. An important feature of this concept is to use the local signal for monitoring the distance between probe and surface. Thus, topographical information, in principle down to atomic resolution, can be obtained in real space. Moreover, the possibility of positioning sharp probes above a surface with angstrom and sub-angstrom precision opens up the exciting possibility of accessing local spectroscopic information, even confined to spots as small as a single atom.

Figure 125. General scheme of scanning probe microscopy

Although a large number of scanning probe microscopy techniques utilizing various signal generation mechanisms has emerged, atomic force microscopy and scanning tunneling microscopy are the most important techniques with a wide range of applications in science and technology.

5.1. Atomic Force Microscopy (AFM)

5.1.1. Principles

Atomic force microscopy (AFM), invented in 1985 by Binnig, Quate, and Gerber [473], [474], belongs to the group of scanning force microscopy (SFM) techniques, which are based on the measurement of different forces (e.g. attractive, repulsive, magnetic, electrostatic, van der Waals) between a sharp tip and the sample surface. Imaging is accomplished by measuring the interaction force by means of the deflection of a soft cantilever while raster-scanning the tip across the surface (Fig. 126). Although various types of forces are encountered when a tip approaches the sample surface, signal generation in AFM is essentially based on interatomic repulsive forces, which are of extreme short range nature (Fig. 127). In the ideal case the tip can be considered to be terminated by a single atom, which means that direct contact of the tip with the sample surface is confined to an extremely small area. As a consequence there is always an interatomic repulsive force at this small contact area due to interpenetration of the electronic shells of the tip and substrate atoms. Since the interatomic repulsive force is influenced by the total electron density around an atom, and not just by particular states of energy as in scanning tunneling microscopy, this force can be used to map the topography of the surface down to atomic dimensions. In addition to this short-range force, long-range forces (e.g., Coulomb forces between charges, dipole – dipole interactions, polarization forces, van der Waals dispersion forces, capillary forces due to adsorbate films between tip and substrate), which can be attractive or repulsive, are also encountered (Fig. 127). Although both types of forces contribute to the total force acting on the probing tip, only the varying repulsive interatomic force

allows high-resolution imaging of surfaces, because of its extremely short range nature. Since long-range attractive forces pull the tip towards the sample surface, they give rise to an increase in the local repulsive force, which can deteriorate the experimental conditions. This can lead, for instance, to artefacts due to sample deformation or, in the worst case, the sample can be destroyed by the tip's scratching across the surface. Hence, it is important to minimize these long range forces (e.g., by imaging under liquids) to achieve very low repulsive forces (nanonewton and less) in the contact area between tip and sample. This is especially important when looking at soft materials, which can be deformed or destroyed easily by the load of the tip.

Figure 126. Principle of AFM. The sample, symbolized by the circles, is scanned by means of a piezoelectric translator. The piezo crystal and the oscillator are only needed for tapping-mode operation.

Figure 127. Schematic view of forces encountered when the tip touches the sample surface. Light circles symbolize tip atoms, and dark circles sample atoms.

The interaction between tip and sample can be described by force – distance curves. The force – distance curve in Figure 128 shows how the force changes when the sample surface approaches the tip. At large separations there is no interaction, and the observed force is zero (straight line between 1 and 2, if we assume that there are no electrostatic charging forces). At position 2 the tip jumps into contact due to attractive van der Waals interaction. As the sample is further moved towards the tip, the total force acting on the cantilever becomes repulsive. When the sample is retracted again, the force is reduced along the line from position 3 to 4. Below the zero-force line in the diagram the net force acting on the cantilever becomes attractive, because the tip is held at the surface due to adhesion. At 4 the adhesion force and the cantilever load are just balanced, and the tip flips off the surface when the sample is further retracted. For AFM measurements, the force can be set along the curve between positions 3 and 4, preferably close to 4 to minimize the contact force. The value of the pull-off force can be reduced significantly by imaging under liquids due to elimination of capillary condensation forces, which pull the tip towards the sample.

Figure 128. Force – distance curve depicting the interaction of the AFM tip with the sample surface. The operating range of the AFM is between positions 3 and 4. For explanation refer to the text.

One option for imaging surfaces under gentler conditions is tapping-mode AFM [475], [476]. In this mode of operation, the cantilever with the tip is driven near its resonance frequency by means of a piezo oscillator (Fig. 126), so that only intermittent contact between tip and sample occurs. In tapping-mode AFM to-

pographic information is retrieved from the amplitude signal of the oscillating cantilever. The advantage of this technique is that, due to the intermittent contact, lateral shear forces can be eliminated. Thus, scratching of soft samples or removal of loosely bound surface features (e.g., particles, thin films) can be avoided.

AFMs can be operated in two different modes: the constant-force mode and the constant-height mode. In the *constant-force mode*, the cantilever deflection, and hence the force, is kept constant by readjusting the sample in the vertical direction to follow the topographic features of the surface. In this mode comparatively large and rough sample areas can be imaged without destroying the tip, the sample surface, or both ("tip crash"), but the scan rates must be kept comparatively low to allow the feedback system to respond to height changes. In the *constant-height mode* the vertical position of the sample is kept constant, and the varying deflection of the cantilever is recorded. In this mode higher scan rates can be achieved, which is advantageous for eliminating thermal drifts in high-resolution imaging, but large scan sizes should be avoided, because tip crashes are possible.

5.1.2. Instrumentation

The following basic components of an AFM can be identified:

- A sharp tip mounted on a soft cantilever
- A detection system for measuring the deflection of the cantilever
- A piezoelectric translator to move the probe relative to the sample
- A feedback system to keep the deflection constant by height readjustment of the probe
- An imaging system to convert the single data points into an image

The tips and the cantilevers have to fulfill a number of requirements. The tip should be very sharp with a small radius of curvature and a high aspect ratio so that it can trace fine details on the surface. The cantilever must be softer than the bonds between the atoms of the sample to achieve a measurable deflection without destructive displacement of surface atoms. Moreover, the resonance frequency should be high to minimize noise due to coupling with low-frequency noise (e.g., vibrations of buildings) from the environment. Low spring constants and high resonance frequencies can only be achieved by making the cantilevers very small. Cantilevers with force constants of less than 0.1 N/m and resonance frequencies up to several hundreds of kilohertz can be produced by the multistep lithographic processes common in microelectronics technology. Such microfabricated cantilevers [477], [478] allow imaging with forces typically in the nanonewton and sub-nanonewton range. These forces are about 10 000 to 100 000 times lower than the force of gravity introduced by a fly (1 mg) sitting on a surface. Commercially available cantilevers are usually made of silicon nitride or single-crystal silicon. The length of such cantilevers is typically 100 to 200 μm, the total size of the integrated tip is on the order of 10 μm, and the radius of curvature at the apex can be as small as 5 – 10 nm.

Figure 129. Schematic view of the deflection sensing system as used in the NanoScope III AFM (Digital Instruments, Santa Barbara, CA). The deflection of the cantilever is amplified by a laser beam focused on the rear of the cantilever and reflected towards a split-photodiode detector.

The force acting on the tip is sensed by measuring the deflection of the cantilever. A large number of options (e.g. tunneling current, interferometry, capacitance, laser-diode feedback) [474] for measuring this deflection have been described, but the most important one is the optical-lever technique [479] depicted in Figure 129. In this technique a laser beam is focused and positioned on the rear of the cantilever. The reflected laser beam is directed towards a double-segment photodiode. As the cantilever deflection, and thus the mirror plane for the laser beam,

changes, the position of the laser beam on the photodiode, and hence the difference signal between the two segments, changes, too. Therefore, the difference signal is a sensitive measure of the cantilever deflection, with a resolution of 0.01 nm.

Figure 130. Cross-section view of a liquid cell for in situ AFM measurements of surface processes

Figure 131. A) AFM image of a PVD gold film on silicon; image size: 1 × 1 µm, depth scale: 30 nm from black to white; B) Atomic-resolution image of the crystallite marked by the arrow in A; image size: 4 × 4 nm; depth scale: 1 nm from black to white

Usually, in AFM the position of the tip is fixed and the sample is raster-scanned. After manual coarse approach with fine-thread screws, motion of the sample is performed with a piezo translator made of piezo ceramics such as. lead zirconate titanate (PZT), which can be either a piezo tripod or a single-tube scanner. Single-tube scanners are more difficult to calibrate, but they can be built more rigidly and are therefore less sensitive towards vibrational perturbations.

In contrast to many other surface analytical techniques, such as scanning electron microscopy, AFM does not require a vacuum. Therefore, it can be operated under ambient conditions and allows processes at solid – gas and solid – liquid interfaces to be directly observed. The latter can be accomplished by means of a liquid cell, shown schematically in Figure 130. The cell is formed by the sample at the bottom, a glass cover holding the cantilever at the top, and a silicone O-ring seal between. Studies with such a liquid cell can also be performed under potential control, which opens up valuable opportunities for electrochemistry [480], [481]. Moreover, imaging under liquids opens up the possibility to protect sensitive surfaces by in situ preparation and imaging under an inert fluid [482].

5.1.3. Applications

The great analytical potential of AFM is based on a number of properties summarized in the following: Atomic resolution can be achieved, but imaging can also be performed on areas larger than 100 µm square. This capability allows overview images to be obtained, which can be used to zoom in on details with high resolution without changing the sample or the instrumental setup, which would make it impossible to find the identical sample position again. For example, Figure 131 A shows an image of a PVD gold film on silicon, which gives a good overview on the size and distribution of the single crystallites, which are typically 100 nm in diameter [483]. The root-mean-square (rms) roughness determined from this image is 3 nm. From XRD measurements it is known that the surface of the gold film is mainly a (111) surface. Atomic-resolution images of the position marked with the arrow in Figure 131 A revealed a gold (111) surface for that specific crystallite

(Fig. 131 B). Although the corrugation in one lattice direction is more prominent, which can be caused by convolution with an asymmetric tip, a hexagonal symmetry can be observed, and the spacings are in good agreement with the expected values (0.29 nm).

A further important advantage of AFM is the fact that images contain direct depth information, which makes the technique a valuable metrological tool. Figure 132 A shows, for example, an AFM image of a structured photoresist on a silicon surface. The pattern observed was produced by ion lithography. Figure 132 B depicts a cross-section profile through the image shown in Figure 132 A. This example nicely demonstrates that the AFM data can be conveniently analyzed by the software to directly measure the height of surface features.

Figure 132. A) AFM image of a photoresist layer on silicon, generated by ion lithography; B) Cross-section profile through the AFM image shown in A

Besides conducting samples insulators can also be imaged readily with AFM without the need to coat them with a conductive film. This means that sample preparation is simple in many cases and that artefacts introduced by the coating process can be avoided. Therefore, a wide variety of organic [484], [485], biological [486], [487], and inorganic insulators [488] can be studied in a straightforward manner. Figure 133 shows as an example the topographic image of an organic filtration membrane. The pores in this Lavsan (polyethylene terephthalate) membrane were produced by α-particle bombardment, and their diameter is approximately 200 nm. Between the pores is a uniform surface with an rms roughness of 7 nm.

Figure 133. AFM image of a Lavsan filtration membrane; image size: $5 \times 5\,\mu m$, depth scale: 500 nm from black to white

An important potential of AFM for surface chemistry is its capability to perform in situ measurements under liquids and in air. This opens up the opportunity to directly investigate surface processes like corrosion, crystal growth, thin-film deposition, and electrochemical processes at electrode surfaces [480–482], [489], [490]. As an example of in situ AFM imaging, Figure 134 shows a series of AFM images depicting the deposition of an octadecylsiloxane (ODS) monolayer on silicon. Such self-assembled monolayers (SAMs) can be obtained by deposition of octadecyltrichlorosilane from toluene [491]. It can be seen that large islands with diameters of typically 5 µm are deposited on the surface right from the beginning of the growth experiment. This indicates that, under the given conditions,

such ordered structures already exist in the deposition solution. Once the uncovered surface area no longer offers sufficient space for deposition of further larger islands, continuing film formation can only proceed by growth of already deposited islands by attachment of smaller units, a process which is comparatively slow. During course of time the growing islands coalesce and it can take up to 1 h or more until full coverage of the surface is reached. From such AFM images surface coverages can also also be evaluated on a quantitative basis. Since AFM is able to reveal the structure of submonolayer islands in such deposition experiments with submicrometer resolution, it has significantly contributed to the understanding of growth mechanisms, which is important for controlling film growth by variation of deposition parameters such as the water content of the precursor solution or the temperature [491].

A shortcoming of AFM is that chemical information or material specific properties cannot be obtained from AFM images directly. However, a number of AFM-related techniques which allow information to be accessed in addition to the topography have been introduced. Friction force microscopy (FFM) or lateral force microscopy (LFM) measures the friction between tip and sample surface. This is of particular interest for research in the field of tribology [492], [493]. The principle of the FFM has also been used in a development called the chemical force microscope (CFM) [494]. In this method the tip is chemically modified to make it sensitive towards different chemical surface compositions. In this way image contrast could be achieved due to variations in adhesion (and thus also in friction) between tip and sample. In Young's modulus microscopy (YMM) [495], differences in the surface elasticity can be accessed by measuring of the response of the tip to the vertical modulation of the sample while the tip is in contact with the surface. The adhesion between tip and sample surface can also be visualized by force – distance curve measurements (Fig. 128) [496–498]. The electric force microscope (EFM) utilizes electrostatic forces or force gradients between a conductive tip and a sample for signal generation. In this way information on surface charges [499], [500], topography, capacitance (dielectric constant), and potential (see [474], and references cited therein) can be obtained. In magnetic force microscopy (MFM) [501], magnetostatic forces are measured by interaction of magnetic domains on a surface with a magnetized tip. MFM is mainly interesting as a tool for applications in manufacturing magnetic storage device [502] and allows magnetic patterns to be imaged with a resolution of ca. 50 nm.

5.2. Scanning Tunneling Microscopy (STM)

5.2.1. Principles

In scanning tunneling microscopy (STM) [470], [471] the probe is a sharp metal tip that is scanned across a conducting surface at distances on the order of typically 1 nm (Fig. 135). A bias voltage of typically a few millivolts is applied between the tip and the sample and leads to a tunneling current on the order of a few nanoamperes. Figure 136 shows what happens when a voltage is applied between two metal electrodes separated by a very small distance. If a voltage V is applied then the Fermi levels E_F are shifted relative each other by an energy eV, where e is the electrostatic charge of an electron. Due to the energy barrier between the two metals, which is on the order of the metal's work function ϕ, at small voltages a conventional current cannot flow. However, because the electrons can be described by wave functions decaying exponentially across the energy barrier, the probability of finding an electron on the opposite side of the barrier is not zero. This phenomenon is known as the quantum mechanical tunneling effect. As a consequence, electrons can flow from occupied states on the negative electrode to unoccupied states on the positive electrode, whereby at small voltages they do not change their energy, which is described as elastic tunneling. The dependence of the tunneling current I_T on the applied voltage V_T and the tip-surface separation s is given by

$$I_T \approx V_T \exp\left(-A\phi^{1/2}s\right) \tag{5.1}$$

where A is a constant given by $A = 2[(2m_e)^{1/2}]/h$ (m_e = mass of an electron). Due to this exponential relation, the tunneling current is an extremely sensitive measure of the separation. For

Table 9. Typical data for the more important techniques of surface and thin-film analysis

example, a variation of the separation by 0.1 nm changes the tunneling current by a factor of approximately 10. This means that in principle variations in the separation of 0.001 nm can be monitored by keeping the current constant within a few percent. However, the tunneling current depends not only on the tip – surface separation, but also on the electronic structure of the surface. This is important when interpreting STM images on the atomic scale, because in that case, in contrast to AFM, in general the image

Figure 135. Principle of STM

no longer simply shows the topography of the surface, but rather a contour map of the local density of states near the Fermi level ($LDOS_{E_F}$) if small voltages in the millivolt range are applied. For larger voltages up to a few volts the density of other electronic states can be imaged. Note that the relations given above are only an approximation under the assumption that the tip and the applied voltage do not influence the electronic structure of the surface. Furthermore, for an exact description, three-dimensional tunneling must be considered to take into account the complex spatial structure of the electronic states (wavefunctions) involved [504].

There are two ways of operating an STM: the constant-current mode and the constant-height mode. In the *constant-current mode*, the tip is scanned across the sample surface at a fixed bias voltage, and the tunneling current is kept constant by readjusting the tip in the vertical direction to follow the topographic features (or, on the atomic level, the local density of states) on the surface. In this mode, comparatively large and rough sample areas can be imaged without destroying the tip, the sample surface, or both ("tip crash"), but the scan rates must be kept comparatively low to allow the feedback system to respond to height changes. For images taken in constant-current mode at a certain bias voltage, the term constant-current topograph (CCT) is sometimes used. In the *constant-height mode* the vertical position of the tip is kept constant and the varying tunneling current is recorded. In this mode higher scan rates can be achieved, which is advantageous for eliminating thermal drifts in high-resolution imaging, however, large scan areas should be avoided, because tip crashes are possible.

Figure 136. Energy level diagram of a tunneling junction [503]

5.2.2. Instrumentation

Figure 137 shows a schematic overview of an STM system consisting of the following basic components:

- A sharp metal tip
- A piezoelectric translator to move the tip relative to the sample
- Control electronics for applying the bias voltage and measuring the tunneling current
- A feedback system to keep the tunneling current constant by height adjustment of the tip
- An imaging system to convert the single data points into an image

The tips used for STM experiments should be sharp and stable. Chemical stability can be

Figure 137. Scheme of an STM system [505]

achieved by using a noble metal. Mechanical rigidity can be attained by using short wires. Alloys of Pt and Ir are frequently used for fabrication of STM tips. They can be produced in a surprisingly simple way just by cutting a metal wire with conventional cutting tools. Due to their high chemical stability, such Pt – Ir tips are well suited for atomic-resolution experiments on flat samples. However, due to their low aspect ratio near the apex they fail to trace steep features and narrow trenches. Therefore, electrolytically etched tungsten tips with higher aspect ratios are sometimes used as an alternative, although they are less stable against oxidation.

Usually, in STM the position of the sample is fixed and the tip is raster-scanned. Like in AFM, after manual coarse approach with fine-thread screws, motion of the tip is performed with a piezo translator made of piezo ceramics like lead zirconate titanate (PZT), which can be either a piezo tripod or a single-tube scanner.

Although physical studies of the electronic structure of surfaces have to be performed under UHV conditions to guarantee clean uncontaminated samples, the technique does not require vacuum for its operation. Thus, in-situ observation of processes at solid – gas and solid – liquid interfaces is possible. This has been utilized, for instance, to directly observe corrosion and electrode processes with atomic resolution [471], [506].

5.2.3. Lateral and Spectroscopic Information

STM images can only be interpreted in terms of surface topography for surface structures with dimensions well above the atomic scale. In general, images taken in constant-current mode deliver contour maps of the local density of states. If the polarity of the sample is negative, then states in the valence band are imaged. For a positive polarity of the sample the distribution of electronic states in the conduction band can be recorded. If different chemical species are present on the surface, the image contrast is further influenced by the varying effective barrier height (work function) at different positions. As an example Figure 138 shows an STM image of a silicon (111) surface with one-third of a silver monolayer on top of it [507]. The high contrast between the silicon surface and the silver islands does not represent the real height of the

islands, which appears exaggerated due to the lower work function in the silver regions. Such local differences in the effective barrier height can be directly imaged by modulating the tip in the vertical direction and recording dI/ds, which according to Equation (5.1) is proportional to $\phi^{1/2}xI$. STM can also yield spectroscopic information by recording dI/dU curves at fixed positions, which is called scanning tunneling spectroscopy (STS). This opens up the opportunity to perform electron spectroscopy with a resolution down to a single atom. An other option for obtaining spectroscopic information is simultaneous recording of STM images at various bias voltages. This can be accomplished by performing point spectroscopy at every image point or by modulating the bias voltage while scanning. In the literature simultaneous recording of images at various bias voltages has been called current imaging tunneling spectroscopy (CITS). An example is the discrimination between Ga and As atoms on a GaAs (110) surface in an atomically resolved STM image by simultaneously recording of two images at reversed bias voltage by Feenstra et al. [508].

5.2.4. Applications

Similar to AFM, an advantage of STM is the fact that a wide range of scan sizes from more than 100 µm down to the atomic level can be covered in one experiment. Because the information is obtained in real space, local defects (e.g. monoatomic defects, steps, dislocations) can be investigated. This clearly is a great advantage compared to diffraction methods, which rely on extended periodic structures and thus show averaged information. Moreover, the possibility to obtain spectroscopic information makes the STM a very valuable tool for studying surface processes on the atomic scale. An instructive example highlighting several figures of merit of STM is given in [509–511] and described below. Figure 139 shows an STM image of the unoccupied states of a Si (111) 7×7 surface exposed to 0.2 L of O_2 at 300 K. Besides the characteristic pattern of the 7×7 structure of the Si (111) surface, pronounced dark and bright spots can be observed as a result of exposure to oxygen. To clarify the mechanistic origin of these spots, tunneling spectra at various atomic sites in the 7×7 unit cell (Fig. 140) were recorded and compared with UPS spectra and theoretical results from tight-binding slab calculations for various adsorption models of oxygen. First of all, Figure 140 shows that the different sites can be clearly distinguished by the respective tunneling spectra, whereas photoemission spectra only deliver averaged information on the electronic structure of the surface. The spectra labeled A, B, and C were obtained on sites that were unchanged by adsorption of oxygen. The spectra labeled D, E, and F were obtained on oxygen-induced dark, bright, and perturbed (gray) adatom sites, respectively. Comparison of these spectra with theoretical calculations and a thorough evaluation, including UPS spectra for different temperatures and oxygen pressures, led to the conclusion that the bright spots (E) are silicon atoms which have maintained their dangling bond but are perturbed by a neighboring oxygen atom inserted in the back bond of the adatom. The dark spots were interpreted as oxygen atoms saturating the dangling bond of a silicon atom which has another oxygen inserted in its back bond. Although this is a rather early work in the field of scanning tunneling spectroscopy, it is still an excellent example for atom-resolved investigation of surface chemistry with STM.

Figure 138. STM image of silicon covered with one-third of a monolayer of silver [507]

STM has, however, not only been applied to metals and semiconductors, but also to a wide variety of organic and biological systems, such as thin films on conducting substrates [484], [485] as well as protein and DNA molecules [512–515].

Figure 139. STM image of a Si (111) 7×7 surface exposed to 0.2 L of O_2 at 300 K. The sample bias voltage was + 2 V. Dark and bright sites generated by oxygen exposure are marked with A and B, respectively [510].

A variant of STM is *spin-polarized STM* (SP-STM), which works with a ferromagnetic tip and can be used to probe surface magnetism with high resolution [516], [517]. Other modifications of STM involve electromagnetic radiation, whereby two basic concepts can be distinguished: measuring of photons generated in the tunneling gap by inelastic tunneling effects [518], [519], which is called *photon-emission scanning tunneling microscopy* (PESTM), and generation of electrical currents by irradiation of the tunneling gap [520–523], which is know as *photon-assisted scanning tunneling microscopy* (PASTM).

6. Summary and Comparison of Techniques

Important surface analytical techniques are summarized and compared in Table 9.

7. Surface Analytical Equipment Suppliers

A large number of suppliers of surface analytical equipment exist; a few provide for several techniques; the majority specialize in just one or two. Only suppliers of equipment for techniques that are discussed in more detail are listed in Table 10. The authors cannot warrant for completeness.

Figure 140. Top: STM image of a region of an O_2-exposed Si (111) 7×7 surface. The sites labeled A, B, and C have not been changed by exposure to oxygen; D, E, and F correspond to oxygen-induced dark, bright, and perturbed (gray) sites, respectively. Bottom: tunneling spectra corresponding to the different sites [510].

1. Introduction to the Field of Sensors and Actuators

When a person suffers the loss of one of the five senses it is recognized as a serious obstacle to carrying out everyday activities. In the case of blindness and deafness the expression "disabled" is even used as an indication of the severity of the loss, just as with those whose limbs (legs or arms) or other crucial body components are incapable of functioning properly. In the animate world generally, sensing and then acting or reacting is closely linked with the very essence of life, where input from some type of sensory system always precedes intelligent action. From the earliest days of mankind it was the availability of a powerful "coping mechanism" that constituted the driving force leading first to intelligent action and later to the unbiased accumulation of knowledge.

Any intellectual information structure capable of producing theories is dependent upon a reliable input of information. Imperfect observations, or perceptual processes subject to frequent errors or some bias, will never provide a satisfactory basis for working theories subject to verification by others. In this respect analytical chemistry can be regarded as one of the cognitive means available to the chemist interested in ascertaining the composition of the material world and the distribution and arrangement of atoms and molecules within a particular sample. Since both the nature and the three-dimensional arrangement of atoms in space determine the characteristics of matter, reliable information with respect to both is crucial for understanding the whole of the material world. This observation is equally valid for the inorganic, the organic, and also the living world. A high level of structured information is essential to the work of most natural scientists. The ability to describe in detail a complex chemical process (e.g., the combustion of fuel in an engine or waste in a municipal incinerator, the synthesis of minerals deep within the earth, or the course of biochemical reactions taking place in living systems) is crucially dependent on the quality of the information available. High technology is impossible without detailed information on the state of the system in question, as has been amply demonstrated in semiconductor technology, where knowledge of the purity of the materials and the state of cleanliness in the production plant is absolutely essential.

Complex and especially dynamic systems involving chemical processes are often described in terms of simplified models. The more chemical information is available, the better will be the model – and consequently the more complete the understanding and control over the system. Chemical analysis constitutes the primary source of information for characterizing the various states of such a system.

As a result of a tremendous increase in the demand for analytical chemical information, the number of analyses conducted for acquiring information about particular samples is increasing dramatically. It is thought that worldwide more than 10^9 analyses are now performed every day – with a double-digit growth rate. The latter because quality control has become a worldwide topic, agreed upon in many international trade contracts. Many complex systems are governed by time-dependent parameters, which makes it essential that as much information as possible be acquired within a particular period of time so that the various reactions taking place within the system can be followed, and to provide insight into the dynamics of the mechanisms involved. Devices designed to permit continuous measurement of a quantity are called *sensors.* Various types of sensors have been developed for monitoring many important *physical* parameters, including temperature, pressure, speed, flow, etc. The number of potential interferences is rather limited in these cases, so it is not surprising that the corresponding sensors offer a level of reliability considerably higher than that for sensors that measure *chemical* quantities (e.g., the concentration of a certain species, the activity of an ion, or the partial pressure of a gaseous material).

There are various major fields of application for chemical sensors: environmental studies, quality control of chemically produced compounds and processed food and biomedical analysis, especially for medical diagnostics. In the field of environmental analysis there is a great demand for the type of continuous monitoring that only a sensor can provide, since the relevant parameter for toxicological risk assessment is always the *dose* (i.e., a concentration multiplied by an exposure time). The study of environmental chemistry also depends upon a continuous data output that provides not only baseline lev-

els but also a reliable record of concentration outbursts. *Data networks* can be used to accumulate multiple determinations of a particular analyte regardless of whether these are acquired simultaneously or at different times within a three-dimensional sampling space (which may have dimensions on the order of miles), thereby providing information about concentration gradients and other factors essential for pinpointing the location of an emission source. The inevitable exponential increase in the number of chemical analyses associated with this need for maximum information threatens to create serious financial and also ecological problems, since most classical analytical chemical techniques themselves produce a certain amount of chemical waste.

Our society is characterized by a population with an average age that is continuously increasing. This has stimulated the widespread biomedical application of chemical sensors for monitoring the health of the elderly without confining them to hospitals. Sensors for determining the concentrations of such key body substances as glucose, creatinine, or cholesterol could prove vitally important in controlling and maintaining personal health, at the same time enhancing the quality of the patient's life. The same principle underlies sensor applications in intensive care wards. Sensors also offer the potential for significant cost reductions relative to conventional laboratory tests, and they can even improve the quality of the surveillance because continuous monitoring can lower the risk of complications. For example, the monitoring of blood potassium levels can give early warning of the steady increase that often precedes an embolism, providing sufficient time for clinical countermeasures.

It should be noted at the outset, however, that the development costs associated with a chemical sensor are typically many orders of magnitude higher than those for a sensor measuring a physical quantity. A satisfactory return on investment therefore presupposes either mass production in the case of low- cost sensors or special applications that would justify an expensive sensor.

Another important field of application for chemical sensors is *process control.* Here the sensor is expected to deliver some crucial signal to the actuators (valves, pumps, etc.) that control the actual process. Fully automated process control is feasible with certain types of feedback circuits. Since key chemical parameters in many chemical or biochemical processes are not subject to sufficiently accurate direct determination by the human senses, or even via the detour of a physical parameter, sensor technology becomes the key to automatic process and quality control. Often the performance of an entire industrial process depends on the quality and reliability of the sensors employed. Successful adaptation of a batch process to *flow-through reactor production technology* is nearly impossible without chemical sensors for monitoring the input, the product quality, and also – an increasingly important consideration – the waste. *Municipal incinerators* would certainly be more acceptable if they offered sensor-based control of SO_2, NO_x, and, even more important, the most hazardous organic compounds, such as dioxines. Compared with the high construction costs for a plant complete with effective exhaust management, an extra investment in sensor research can certainly be justified.

These few examples illustrate the increasing importance of chemical sensor development as a key technology in various closed-looped sensor/actuator-based process control applications. Rapid, comprehensive, and reliable information regarding the chemical state of a system is indispensable in many high technology fields; for this reason there is also an increasing need for intelligent or "smart" sensors capable of controlling their own performance automatically.

Finally, there is an urgent and growing demand for analytical chemists and engineers skilled in producing reliable chemical sensors delivering results that are not only reproducible but also accurate (free of systematic errors attributable to interferences from the various sample matrices).

2. Chemical Sensors [1–9]

2.1. Introduction

Until the introduction in the 1980s of the lambda-(λ) probe [10–12] for oxygen measurement in the exhaust systems of cars employing catalytic convertors (see Section 2.2.3), the prototype for the most successfully applied chemical sensor was certainly the electrochemical

pH electrode, introduced over 50 years ago and discussed in detail in Section 2.3.1.1. This device can be used to illustrate the identification and/or further optimization of all the critical and essential features characterizing sensor performance, including reversibility, selectivity, sensitivity, linearity, dynamic working range, response time, and fouling conditions.

Electrochemical electrodes for chemical analysis have actually been known for over 110 years (the Nernst equation was published as early as 1889), and they can therefore be considered as the forerunners of chemical sensors. In general, a chemical sensor is a small device placed directly on or in a sample and designed to produce an electrical signal that can be correlated in a specific way with the concentration of the *analyte,* the substance to be determined. If the analyte concentration varies in the sample under investigation, the sensor should faithfully follow the variation in both directions; i.e., it should function in a reversible way, and it should deliver analytical data at a rate greater than the rate of change of the system (quasi-reversible case). From the standpoint of practical applications, complete and fast reversibility is relatively unimportant so long as measurements (even readings of such as from a dosimeter) are acquired with sufficient rapidity compared with changes in the analyte concentration that are to be followed. Another restriction arises

from the demand for a reagent-free measurement: an extremely selective or specific cooperation between the analyte atom, ion, or molecule and the surface of a receptor-like sensor element must then be the sole basis for gaining information about the analyte concentration.

The general construction principle of a chemical sensor is illustrated in Figure 1. The most important part is the *sensing element* (receptor) at which the molecular or ionic recognition process takes place, since this defines the overall selectivity of the entire sensor. The sensing-element surface is sometimes covered by an additional surface layer acting as a protective device to improve the lifetime and/or dynamic range of the sensor, or to prevent interfering substances from reaching the sensing-element surface. The analyte recognition process takes place either at the surface of the sensing element or in the bulk of the material, leading to a concentration-dependent change in some physical property that can be transformed into an electrical signal by the appropriate transducer. The transducer cannot itself improve the selectivity (exceptions are transducer like electrochemical electrodes which intrinsically deliver an analyte proportional signal), but it is responsible for the sensitivity of the sensor, and it functions together with the sensing element to establish a dynamic concentration range. The electrical signal of the transducer is usually amplified by a device positioned close to the transducer or even integrated into it. If extensive electrical wiring is required between the sensor and the readout – control unit, the electrical signal might also be digitized as one way of minimizing noise pick-up during signal transmission. Several chemical signals produced by multiple sensing elements, each connected to its own specific transducer, can be transmitted via modern multiplexing techniques, which require only a two-wire electrical connection to the control unit also delivering the electrical power ("Bus"-technique in German).

If a biochemical mechanism (mostly enzymatic catalysis, immuno-chemical reaction or complementary DNA hybridization) is used in the molecular recognition step, the sensor is called a *biosensor.* Systems of this type are dealt with in Chapter 3.

Key features of chemical sensors subject to specification are, in order of decreasing importance:

1) Selectivity
2) Limit of detection (LOD) for the analyte
3) Accuracy (trueness – a new English term – more important than reproducibility)
4) Sensitivity (slope of the calibration curve)
5) Dynamic response range
6) Stability
7) Response time
8) Reliability (maintenance-free working time)
9) Lifetime

Selectivity. The *selectivity* of a chemical sensor toward the analyte is often expressed in terms of a dimension that compares the concentration of the corresponding interfering substance with an analyte concentration that produces the same sensor signal. This factor is obtained by dividing the sensitivity of the sensing device toward the corresponding interfering substance

Figure 1. Schematic arrangement of a typical chemical or biochemical sensor [13]

(= slope of the calibration curve; see below) by the sensitivity for the analyte. Typical selectivities range from 10^{-3} to $<10^{-12}$ the last extremely small value stands for the sodium error of classical pH-glass-electrodes. In order to estimate the error attributable to limited selectivity the concentration of the interferent must be multiplied by the selectivity coefficient. If, for example, a sodium-selective glass electrode shows a typical selectivity coefficient toward potassium ions on the order of 10^{-3}, a thousand-fold excess of potassium- over sodium-ion concentration would produce an equivalent sensor signal, therefore doubling the reading and leading to an error of 100 %. It should be noted, however, that such selectivities are themselves concentration- and matrix-dependent and often depends on the way they are determined. This means that near the limit of detection of a particular sensor an interfering species will disrupt the measurement of an analyte to a greater extent than it will at higher concentrations. Therefore, response factors can rarely be used for correction purposes.

The selectivity is the most important parameter associated with a chemical sensor since it largely determines the trueness of the analytical method. Trueness (or *accuracy*) is more than simply precision, repeatability, or reproducibility: it represents agreement with the true content of the sample. This is the concentration found independent of the method, the time, the analyst, the laboratory, the country, etc. and is demanded in international trade agreements as comparability. All the other parameters mentioned are subject to systematic error, which can only be recognized if an analyte is determined by more than one method. Since selectivity is always limited, all chemical sensors are prone to report higher concentrations than a sample actually contains. In the case of environmental analysis this positive error can be regarded as a safety margin if relevant interferents are also present. In such a situation the sensor acts as a probe for establishing when a sample should be taken to be analyzed in the laboratory. The reproducibility of chemical sensor measurements is often well below 5 % relative.

However, it should also be noted that sensing elements are subject to poisoning, resulting in a diminished response for the analyte. Sensor poisons are substances that either cover the sensing surfaces, thereby influencing the analyte recognition process or, in the case of catalytic sensors, decrease the activity of the catalyst. Since these fouling effects are not linear, predictable, or mathematically additive, great care is necessary whenever data from a sensor array are treated by the methods of mathematical data management (e.g., pattern recognition, neural networks, etc.). The influence of sensor poisoning can be completely different and unpredictable for every single sensing element. There is no simple theory that permits the transfer of poisoning effects with respect to one sensing element to other parts of a sensing array as a way of avoiding recalibration. Thus, any attempt to overcome insufficient selectivity by the use of a sensor array with multiple sensor elements displaying slightly differing selectivities for the analyte and the interferents, followed by the application of chemometrics to correct for selectivity errors, is very dangerous in the context of unknown and variable sample matrices. Unfortunately, this is usually the situation in environ-

mental analysis. In the learning and/or calibration phase of sensor-array implementation it is essential that the sample matrix be understood. In the case of a known matrix and a closed system, and if the number of possible interferents is > 5, the number of calibration steps (involving different mixtures of the interfering compounds, selected to cover all possible concentration and mixture variations) required to provide reliable information on the 5-dimensional response space of the sensor array for a $5 + N$ array is extremely large (usually several hundred). With real samples the time necessary for calibrating the sensors might exceed the period of stability. Since with open environmental systems the type and number of interferents is not known, any attempt to correct for inadequate sensor selectivity by use of a sensor array increases the risk of systematic errors. This assertion is valid for every type of mathematical data treatment (pattern recognition, neural networks, etc.) for samples of unknown and/or variable matrices. However, for trace analysis in the sub-ppm range all analytical methods (with the exception of isotope dilution) are subject to systematic errors, as has been demonstrated with interlaboratory comparison tests using even the most sophisticated techniques [14]. Therefore one should not expect an accuracy of better than 1 – 5 % relative from sensor measurements.

Limit of Detection (LOD) for the Analyte. In analytical chemistry the *limit of detection* (LOD) is exceeded when the signal of the analyte reaches at least three times the general noise level for the reading. No quantitative measurement is possible at this low concentration; only the presence of the analyte can be assumed with a high probability (> 99 %) in this concentration range. The range of quantification ends at ten times the LOD. Therefore, the LOD of an analytical instrument must always be ten times smaller than the lowest concentration to be quantified. It is worth mentioning in this context that LOD values reported by most instrument manufacturers disregard the influence of interfering compounds. Furthermore, the actual LOD is often worse than published values with simple mono-analyte solutions when an analyte must be determined within its characteristic matrix (e.g., a pollution site, urine, or blood).

In some cases with extremely sensitive sensors a zero-point calibration might be difficult to perform, because traces of the analyte would always be present or might easily be carried into the calibration process by solvents or reagents. The lowest *measurable* level is then called the *blank value.* The LOD is then defined as three times the standard deviation of the blank value, expressed in concentration units (not in the units of the signal, as is sometimes improperly suggested).

Normally the LOD becomes worse as a sensor ages.

Sensitivity. As mentioned above, the *sensitivity* of a sensor is defined by the signal it generates, expressed in the concentration units of the substance measured. This corresponds to the slope of the corresponding calibration curve when the substance is the analyte, or to the so- called response curve for interferents. With some sensors the sensitivity rises to a maximum during the device's lifetime. A check of the sensitivity is therefore a valuable quality-assessment step. Intelligent sensors are expected to carry out such checks automatically in the course of routine performance tests. Since in most cases the sensitivity depends on such other parameters as the sample matrix, temperature, pressure, and humidity, certain precautionary measurements are necessary to ensure that all these parameters remain constant both during calibration and in the analysis of real samples.

Dynamic Response Range. The *dynamic response range* is the concentration range over which a calibration curve can be described by a single mathematical equation. A potentiometric sensing device follows a logarithmic relationship, while amperometric and most other electrochemical sensors display linear relationships. Both types of signal-to- concentration relationship are possible with optical sensors; in absorption measurements it is the absorbance with its logarithmic base that is the determining factor, whereas a fluorescence measurement can be described by a linearized function. The broader the concentration range subject to measurement with a given sensing system, the less important are dilution or enrichment steps during sample preparation. The measurement range is limited by the LOD at the low concentration end, and by

saturation effects at the highest levels. Modern computer facilities make it possible also to use the nonlinear portion of a calibration curve as a way of saving sample preparation time, but analytical chemists are very reluctant to follow this course because experience has shown that the initial and final parts of a calibration curve are generally most subject to influence by disturbances (electronic and chemical). A good chemical sensor should function over at least one or two concentration decades. Sensors with excellent performance characteristics include the lambda oxygen probe and the glass pH electrode, both of which cover analyte concentration ranges exceeding twelve decades!

Stability. Several types of signal variation are associated with sensors. If the signal is found to vary slowly in two directions it is unlikely to be regarded as having acceptable stability and reproducibility, especially since it would probably not be subject to electronic correction.

Output variation in a single direction is called *drift.* A steadily drifting signal can be caused by a drifting zero point (if no analyte is present) and/or by changes in sensor sensitivity (i.e., changes in the slope of the calibration curve). Drift in the sensor zero-concentration signal (*zero-point drift*) can be corrected by comparison with a signal produced by a sensor from the same production batch that has been immersed in an analyte-free solution.

When drift observed in a sensor signal is attributable exclusively to zero-point drift, and there has been no change in the sensitivity, a one-point calibration is permissible: that is, either the instrumental zero point must itself be adjusted prior to the measurement, or else the sensor signal for a particular calibration mixture must be recorded. Assuming there is no change in the slope of the calibration curve, this procedure is equivalent to effecting a parallel shift in the calibration curve. If the sensor is routinely stored in a calibrating environment between measurements then such a one-point calibration becomes particularly easy to perform.

Special attention must be directed toward the physical and chemical mechanisms that cause a sensor signal to drift. Differential techniques are satisfactory only if the effect to be compensated has the same absolute magnitude and the same sign with respect to both devices. A consideration often neglected in potentiometry is proper functioning of the reference electrode. Several authors [15–17] have suggested that in ion-selective potentiometry a "blank membrane" electrode (one with the same ion-selective membrane composition as the measuring electrode but without the selectivity-inducing electroactive compound) would create the same phase-boundary potential for all interfering compounds as the measuring electrode itself. This is definitely not the case, however. At the measuring electrode, analyte ions establish a relatively high exchange-current density, which fixes the boundary potential. The effect of a particular interfering ion will depend on its unique current–voltage characteristics at such an interface. Therefore, interfering ions may establish different phase-boundary potentials depending on the particular mixed potential situations present at the membranes in question, which means that a differential measuring technique will almost certainly fail to provide proper compensation.

If both the zero point of a sensor and its sensitivity change with time, a two-point calibration is necessary. The combination of a changing slope for the calibration curve and a change in the intercept is generally unfavorable, but this is often the situation with catalytic gas sensors. If the slope of the calibration curve also depends on the sample matrix, only standard addition techniques will help.

The stability of a chemical sensor is usually subject to a significant aging process. In the course of aging most sensors lose some of their selectivity, sensitivity, and stability. Some sensors, like the glass pH electrode, can be rejuvenated, while others must be replaced if certain specifications are no longer fulfilled.

Response Time. The *response time* is not defined in an exact way. Some manufacturers prefer to specify the time interval over which a signal reaches 90 % of its final value after a tenfold concentration increase, while authors sometimes prefer the 95 % or even 99 % level. The particular percentage value chosen represents a pragmatic decision, since most signal–time curves follow an exponential increase of the form:

$$\text{signal} \times \left(1 - \mathrm{e}^{-kt}\right)$$

where the true final value is unknown and/or will never be reached in a mathematical sense. Therefore, specification in terms of the time constant k is clearer. This corresponds to the time required for a signal to reach about 67 % of its final value, which can be ascertained without waiting for a final reading: as the slope of the curve ln (signal) vs. time. If the response is constant and independent of the sample matrix, this equation can be used to calculate a final reading immediately after the sensor has been introduced into the sample.

Typical response times for chemical sensors are in the range of seconds, but some biosensors require several minutes to reach a final reading. At the other extreme, certain thin-film strontium titanate oxygen sensors show response times in the millisecond range.

The response time for a sensor is generally greater for a decreasing analyte concentration than for an increasing concentration. This effect is more pronounced in liquids than in gaseous samples. Both the surface roughness of the sensor and/or the dead volume of the measuring cell have some influence on the response time. Small cracks in the walls of a measuring cell can function as analyte reservoirs and diminish the rate of analyte dilution.

With certain sensors the response time can also depend on the sample matrix. In the presence of strongly interfering substances the response time for a chemical sensor might increase as a result of an increase in the time required to reach final equilibrium.

Reliability. There are various kinds of reliabilities. One involves the degree of trust that can be placed in an analytical result delivered by a particular chemical sensor. Another is a function of the real time during which the sensor actually performs satisfactorily without a breakdown and/or need for repair.

There is no way to judge fairly the analytical reliability of a chemical sensor, since this depends strongly upon the expert ability of the analyst to choose a suitable sensor and a suitable sample preparation routine in order to circumvent predictable problems.

With respect to the first generation of sensors, the ion-selective electrodes, the experience of many users has led to the following "reliability hit list", with the most reliable devices cited first: glass pH electrodes, followed by fluoride, sodium glass, valinomycin-based potassium, sulfide, and iodide electrodes, and culminating in the electrodes for divalent ions. In a general way, sometimes very personal judgements regarding reliability have always been linked to a particular sensor's specificity toward the analyte in question.

Reliability can be improved considerably if analytical conclusions are based on measurements obtained by different methods. For example, it is possible to determine sodium either with an appropriate glass-membrane electrode or with a neutral carrier-based membrane electrode. If both give the same analytical results, the probability of a systematic error is very low. Likewise, potassium might be measured using selective membrane electrodes with different carrier molecules. This is of course different from analysis based on a sensor array, in which the selectivities of the individual sensors differ only slightly, and different also in the sense that no correction procedure is invoked in case two results are found to disagree. Use of the Nernst–Nikolsky equation (see Section 2.3.1.1), together with the introduction of additional electrodes for determining the main interferents, has been shown to be an effective way of correcting errors in the laboratory with synthetic samples. Since selectivity numbers (i.e., parameters like the selectivity coefficient) are influenced by the sample matrix through its ionic strength, content of surface-active or lipophilic compounds, or interfering ions, it is dubious whether data from real environmental samples should be corrected by this method.

The length of time over which a chemical sensor can be expected to function reliably can be remarkably great (in the range of years), as in the case of glass-membrane or solid-state membrane electrodes, the lambda probe (Section 2.2.3), and the Taguchi gas sensor (see Section 2.2.2). On the other hand, a biosensor that depends upon a cascade of enzymes to produce an analyte signal will usually have a short span of proper functioning (a few days only). Potentiometric ion-selective membrane electrodes and optical chemosensors have lifetimes of several months. In the case of biosensors it should be noted that anything that changes the quaternary space-orientation of the recognition biomolecules will destroy the proper function-

ing of the sensor. Enzymes can be influenced by such factors as pH, certain heavy-metal ions, certain inhibitors, and high temperature (resulting in denaturation).

Lifetime. As already mentioned above, some rugged solid-state sensors have *lifetimes* of several years. Certain sensors can also be regenerated when their function begins to deteriorate. The shortest lifetimes are exhibited by biosensors. Ion-selective electrodes and optical sensors based on membrane-bound recognition molecules often lose their ability to function by a leaching-out effect. In optical sensors the photobleaching effect may also reduce the lifetime to less than a year. On the other hand, amperometric cells work well for many years, albeit with restricted selectivities.

Problems associated with inadequate lifetimes are best overcome with mass-produced miniaturized replacement sensors based on inexpensive materials. Minimizing replacement costs may well represent the future of biosensors. Installation of a new sensor to replace one that is worn-out can also circumvent surface fouling, interfering layers of proteins, and certain drift and poisoning problems. The integrated optical system IOS developed at the ICB Muenster and described in Section 3.3.2 has shown for the first time how to work with pre-calibrated low-cost immuno-chips with long storage capability.

Comparison of Sensor Data with that Obtained by Traditional Analytical Methods. It is extremely difficult to compare sensor data with traditional data; indeed, generalizations of this type are rarely possible anywhere in the field of analytical chemistry. Sensor developers are often confronted with the customer's tendency to consider use of a sensor only if all else has failed. This means that the most adverse conditions imaginable are sometimes proposed for the application of a chemical sensor. It is also not fair to compare a device costing a few dollars with the most expensive and sophisticated instrumentation available, nor is it appropriate to compare the performance of a chemical sensor with techniques involving time- consuming separations. In this case only the corresponding detector should be compared with the sensor. Sometimes the very simple combination of a selective chemical sensor with an appropriate separation technique is the most effective way to obtain the redundant data that offer the highest reliability.

Chemical sensors are generally superior to simple photometric devices because they are more selective or faster (as in the case of optical sensors based on the photometric method), more flexible, more economical, and better adapted to continuous sensing. The latter advantage can also be achieved by traditional means via flow-through measuring cells, but this leads to a waste of material and sample, and also to the production of chemical waste. Reagent-free chemical sensors show their greatest advantages in continuous-monitoring applications, in some of which they are called upon to fulfill a control function without necessarily reporting an analytical result, as in the case of the lambda probe described below (Section 2.2.3).

2.2. Molecular Recognition Processes and Corresponding Selectivities

In any sensing element the functions to be fulfilled include sampling, sample preparation, separation, identification, and detection. Therefore, successful performance in these tasks largely determines the quality of the chemical sensor as a whole. Selective recognition of an analyte ion or molecule is not an easy task, since more than five million compounds are known, and a real sample may contain hundreds of potentially interfering compounds. Recognition can be accomplished only on the basis of unique characteristics of the analyte in question. Several different recognition processes are relevant to the field of chemical sensors, ranging from energy differences (in spectroscopy) to thermodynamically determined variables (in electrochemistry), including kinetic parameters (in catalytic processes). The most specific interactions are those in which the form and the spatial arrangement of the various atoms in a molecule play an important role. This is especially true with biosensors based on the complementary (lock-and-key) principle. Here the analyte molecule and its counterpart have exactly complementary geometrical shapes and come so close together that they interact on the basis electrostatic interaction or with weak van der Waals interaction

forces. Apart from biomolecules, supramolecular chemistry has been given increased attention [18], [19].

2.2.1. Catalytic Processes in Calorimetric Devices

Pellistors are chemical sensors for detecting gaseous compounds that can be oxidized by oxygen. A catalyst is required in this case because the activation energy for splitting a doubly-bonded oxygen molecule into more reactive atoms is too high for the instantaneous "burning" of oxidizable molecules. In most cases platinum is the catalyst of first choice because of its inertness. The principle underlying oxidizable-gas sensors involves catalytic burning of the gaseous analyte, which leads to the production of heat that can in turn be sensed by various temperature-sensitive transducers. Often what is actually measured is the increase in electrical resistance of a metal wire heated to an elevated temperature (ca. 300 – 400 °C) by the current flowing through it. However, it is also possible to use more sensitive semiconductor devices or even thermopiles in order to register temperature changes of $< 10^{-4}$ °C.

In order to understand the selectivity displayed by a pellistor toward various flammable compounds it is necessary to consider the elementary steps in the corresponding catalytic oxidation of analyte at the catalyst surface. Since this is in fact a surface reaction, various adsorption processes play a dominant role. First, oxygen must be adsorbed and chemisorbed, permitting the oxygen double bond to be weakened by the catalyst. Then the species to be oxidized must also be adsorbed onto the same catalyst surface where it can subsequently react with the activated oxygen atoms. The process of adsorption may follow one of two known types of adsorption isotherms, as reflected in the calibration curves for these devices. An equilibrium consisting of adsorption, catalyzed reaction, and desorption of the oxidized product leads to a constant signal at a constant analyte concentration. The sensor response function is influenced by any change in the type or number of active surface sites, since this in turn affects both the adsorption processes and the catalytic efficiency. Likewise, compounds that have an influence on any of the relevant equilibria will also alter the calibration parameters. Especially problematic are strongly adsorbed oxidation products, which lower the turnover rate of analyte molecules and thus the sensitivity of the gas sensor.

Given the sequence of events that must occur when an organic molecule is oxidized by atmospheric oxygen, thereby delivering the heat that is actually to be measured, one can readily understand the importance of changes in the adsorption and desorption equilibria. The selectivity observed with such a calorimetric device arises not because some gas reactions are associated with larger enthalpy changes than others, but rather because those gas molecules that exhibit the most rapid adsorption and desorption kinetics are associated with the highest turnover rates. The latter of course depend on molecular-specific heats of ad- and desorption, which have a major influence on the overall reaction kinetics. A change in these specific heats always results in a corresponding change in sensor selectivity. Consequently, any change in the catalyst material, its physical form, or its distribution within the mostly ceramic pellet will in turn alter the gas selectivity and sensitivity. The same is true for variations in the working temperature. On the other hand, nonreacting compounds can also influence a sensor's response and thereby the calibration function if they in some way affect one of the relevant equilibria and/or the catalytic power of the catalyst. Catalyst poisons such as hydrogen sulfide or organic silicon compounds show a strongly detrimental effect on sensor response.

Summarizing the selectivity characteristics of these calorimetric gas sensors, any gas will be subject to detection if it can be catalytically oxidized with a high turnover rate by atmospheric oxygen at elevated temperature. From a kinetic point of view, smaller molecules like carbon monoxide or methane are favored. In contrast to biosensors there is here no precise molecular "tight-fit" recognition of the geometrical form of the analyte. Thus, the selectivity of this type of gas sensor is rather limited. Differences in the often reaction-rate controlled adsorption and desorption processes for different oxidizable gas molecules are not sufficiently large to allow selective detection of only a single compound. However, this is not necessarily a disadvantage in certain sensor applications, such as detecting

the absence of explosive gases (especially important in the mining industry) or carbon monoxide in an automobile garage. In the latter case any positive error resulting from gasoline interference could in fact be regarded as providing a safety margin, since unburned gasoline should be absent from such locations as well.

2.2.2. Reactions at Semiconductor Surfaces and Interfaces Influencing Surface or Bulk Conductivities

Introduction. Since the early 1960s it has been known that the electrical conductance of certain semiconductor materials such as binary and ternary metal oxides (e.g., SnO_2 [20], ZnO [21], Fe_2O_3 [22] – all of which are *n*-semiconductor materials – and CuO or NiO [23] – *p*-semiconductors) depends on the adsorption of gases on their solid surfaces. The underlying principle here involves a transfer of electrons between the semiconductor surface and adsorbed gas molecules, together with charge transduction in the interior of the material. Typical gases detected by semiconducting devices include oxidizable substances such as hydrogen, hydrogen sulfide, carbon monoxide, and alkanes (SnO_2, ZnO, etc.), as well as reducible gases like chlorine, oxygen, and ozone (NiO, CuO).

In 1967 both Shaver [24] and Loh [25] described effects achievable with oxide semiconductors modified by the addition of noble metals (e.g., Pt, Pd, Ir, Rh), and since that time the sensitivity and selectivity of semiconductor sensing devices has been significantly enhanced. Intense efforts in this direction, coupled with the further addition of metal oxides [26–28], resulted in widespread application of semiconductor gas sensors beginning in the 1970s.

One of the earliest SnO_2 sensors, designed by N. Taguchi, is referred to as the "Figaro sensor" (see below). Sensors of this type make it possible to detect as little as 0.2 ppm of an oxidizable compound such as carbon monoxide or methane [29]. Nevertheless, certain details of the associated sensing mechanism are still not fully understood theoretically. An important aim is to overcome limitations of the present generation of sensors, especially instability, irreproducibility, and nonselectivity [30].

Construction and Characterization of Semiconductor Sensors. Semiconductor gas sensors are characterized by their simple construction. A schematic overview of the construction principle of a homogeneous semiconducting gas sensor is provided in Figure 2 A [31]. Sensor operation is based on a change in the surface resistance (or conductance) of an oxidic microcrystalline semiconductor in the presence of interacting gases. A time-dependent record reflecting transient exposure of a sensor to a gas leading to an increase in conductance is illustrated in Figure 2 B. The sensitivity of a semiconductor sensor is strongly affected by its operating temperature, which is normally in the range 200 – 400 °C. Chemical regeneration of the oxide surface is possible by a reheating process.

(with permission from Elsevier, Amsterdam)

A commercial sensor of the "Figaro" type (TGS 813) is shown in Figure 3 A; 400 000 such sensors had already been sold in 1988 [32].

Miniaturization leads to a more modern version of the SnO_2 sensor, normally prepared by thick-film techniques (Fig. 3 B) in which thin

SnO_2 films, insulator layers (SiO_2), and integrated heating films are sputtered onto silicon substrates. This approach is compatible with high rates of heating and low-cost production [13].

Working Principles and Theory. The mechanisms responsible for semiconductor gas-sensor operation can be divided into two classes. The first class involves changes in bulk conductance (transducer function), while the second relies on changes in surface conductance (receptor function). The physical phenomena associated with these two mechanisms are shown schematically in Figure 4 A [33]; Figure 4 B addresses the same problem at the microstructural level [34].

The description of functional principles that follows relates directly to *n*-semiconductors, but its application to *p*-semiconductors is straightforward. In a first step, oxygen molecules from the air form a layer of more or less strongly adsorbed (chemisorbed/ionisorbed) oxygen molecules at the surface, resulting in a local excess of electrons. In other words, oxygen acts as a *surface acceptor,* binding electrons from the surface space – charge layer. With respect to the principal energy states (levels) of the electrons in the surface space – charge layer, ionisorption results in a decrease in the electron concentration and an increase in the electronic energy (Fig. 5) [32].

Subsequent reaction with reducing gases (e.g., CH_4 or CO) leads to an increase in charge density (and therefore an increase in conductivity), associated with three possible mechanisms [23], [31], [35]:

1) Adsorption of the reducing molecules as donors, causing electrons to be shifted into the conductance band of the oxide

Figure 4. A) Illustration of the physical and chemical phenomena involved in the transduction of a change in the gaseous atmosphere into a change in conductance of a ceramic oxide (with permission from Adam Hilger, Bristol); B) Surface reactions (receptor function) may occur between adsorbed species and defects in the solid (transducer function), between different adsorbed species, or between gas molecules and adsorbed species (or any or all of these together), and the surface reaction may involve a catalyst [33], [34] (with permission from Elsevier, Amsterdam)
a) Element (output resistance change); b) Microstructure (transducer function); c) Surface (receptor function)
D = Particle size; X = Neck size; L = Thickness of space – charge layer

2) Reaction of the reducing molecules with ionisorbed oxygen under conditions leading to the production of bound electrons
3) Reduction of oxidic oxygen by the reducing molecules, resulting in oxygen vacancies which act as donors, thereby increasing the conductance

Cases 1) and 2) alter the amount of charge stored in the *surface states*, and therefore the amount of charge of opposite sign in deeper parts of the region. For a theoretical derivation of the relationship between the conductance of a semiconducting oxide layer and the composition of the gaseous surroundings, the following facts must be considered [30], [36]:

Oxygen must be present; that is, these sensors respond only to nonequilibrium gas mixtures containing both combustible gases (CO, hydrocarbons, H_2, etc.) and oxygen.

There exists a temperature of maximum response; that is, the relative change in conductivity upon introduction of a combustible gas increases with increasing temperature, but falls to zero at sufficiently high temperatures.

With respect to the relationship between conductivity (σ) and gas partial pressure, Equation (1) has been found to apply:

$$\sigma \sim p^{\beta} \tag{1}$$

where p is the partial pressure of the combustible gas and β is generally in the range 0.5 – 1.0 depending on the mechanism.

This microscopic model is limited to idealized thin films (10 – 100 nm of, for example, SnO_2). Here the gas – solid interactions can be described in terms of the electronic surface states, which are related to energy levels in the band gap model (Fig. 5). Other surface phenomena involved are lattice defect points, trace impurities, and material segregations near the surface. Crystal dislocations and adsorbed atoms or molecules also play an important role in states

at the gas – solid interface. As far as *n*-semiconductors are concerned, both adsorbed hydrogen and oxygen vacancies can function as surface donors, whereas ionisorbed oxygen is a surface acceptor. A surface potential difference develops as a consequence of negatively charged adsorbed oxygen (O_2^- and O^{2-}) and positively charged oxygen vacancies within the space – charge region below the surface layer. Increasing the amount of negatively charged oxygen at the surface causes the surface potential to increase up to the Fermi level (the highest level occupied by electrons). This defines the surface potential and represents the surface state, but the precise magnitude of the potential is a function of the oxygen partial pressure. The distribution of the various adsorbed oxygen species depends on the temperature, and is influenced by the presence of hydrogen and other gaseous compounds. With respect to the two possible charged oxygen species, O_2^- and O^-, it can be assumed that only O^- is reactive, and that the rate of interconversion of the species is low compared to the rate of the surface combustion reaction, consistent with the following kinetic scheme [33], [37]:

At low temperature the adsorbed species is mainly O_2^-, which is converted into O^- when the temperature is increased above 450 K.

If a combustible gas R reacts with the adsorbed oxygen species, a steady state occupancy Θ of the surface state is established, which is less than the equilibrium occupancy in air. The following mechanism can be assumed:

$$n' + 1/2\,O_2(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} O^-(s)$$

$$R(g) + O^-(s) \xrightarrow[k_2]{} RO(g) + n'$$

where n' denotes a conductance electron.

Necessary conditions for sensitivity with respect to the partial pressure p of the combustible gas are then:

$$k_{-1} << k_2 p\,(R) \text{ and } k_1 p\,(O_2)^{1/2} << k_2 p\,(R) \quad (2)$$

in which case

$$\Theta = \frac{k_1 p\,(O_2)^{1/2}}{k_{-1} + k_1\,(O_2)^{1/2} + k_2 p\,(R)} \quad (3)$$

The third case described above is somewhat different: here the observed effect is related to a change in bulk conductance as a function of stoichiometric changes in oxygen activity in the interior of the crystal lattice. The change in conductivity can be described by the relationship [33]:

$$\sigma = \sigma_0 \exp\,(E_A/kT)\,p\,(O_2)^{\frac{1}{n}} \quad (4)$$

where σ_0 denotes the electrical conductivity in air, k denotes the Boltzmann constant, T is the temperature in Kelvin, E_A is an activation energy, and the sign and value of n depend on the nature of the point defects arising when oxygen is removed from the lattice. At low temperature (< 500 °C) the rate-determining step is interfacial combustion, whereas oxygen vacancies within the lattice dominate at higher temperatures below ca. 1000 °C.

Thus, the observed overall conductance represents a combination of surface effects (both electronic and ionic) together with grain-boundary and volume-lattice effects. The principles elaborated above have been applied widely in the control of oxygen in combustion processes at high temperatures, as in automobile engines.

Parameters. Under a constant set of conditions (temperature, air, pressure, humidity, etc.) the ratio of the conductance in sample air to that in pure air (G/G_0) is proportional to the analyte concentration (Fig. 6). Apart from the concentration of adsorbed gases, other parameters, both physical and chemical, may also have an influence on the conductance and the optimum working conditions. Considering both components of the conductance change described above, the most important factors influencing conductance are:

1) The microstructure of the semiconducting particles and the surface composition, both of which are characterized by the crystallite size D, the grain-size distribution, and the coagulation structure, all subject to some control through the inclusion of additives.
2) The working temperature of the material, which has a unique optimum (maximum)

value for a particular material composition, and must therefore be determined separately for every analyte gas and every substrate composition (Fig. 7).

Figure 6. Sensitivity data from commercial SnO_2-based sensors, with sintered layers containing stabilizing additives like SiO_2 (conductance as a function of CO and CH_4 concentration in air); the Type 711 sensor probably operates at a lower temperature and incorporates different catalytically active additives than the Type 813 sensor [31], [38] (with permission from Elsevier, Amsterdam)
– – – – – Sensor Type 711; ——— Sensor Type 813; × = CH_4; o = CO

Tin dioxide has become the favorite material for sensor applications of this type because of its simple preparation and high sensitivity at low operating temperature. Commercially available sensors are usually sintered $\geq 700\,°C$ to ensure sufficient mechanical strength; the cross-sectional diameter of the SnO_2 particles is typically ≥ 20 nm. Unfortunately there is a sharp decrease in gas sensitivity (corresponding to a decrease in the resistance of the SnO_2) when the particle size D increases beyond about 6 nm (Fig. 8 A) [34]. Additives such as barium, phosphorus, or lanthanum oxides can be used to restrict thermal growth of the SnO_2 particles to a limit of ca. 10 nm (Fig. 8 B) [34].

Figure 7. Sensor response to reducing gases (1000 ppm in air) as a function of temperature (sintered layer of SnO_2, thickness 0.05 mm, 0.05 wt % Sb; based on [39], [31]) (with permission from Elsevier, Amsterdam)

Various approaches have been applied to interpreting the parameters influencing gas sensitivity. Models that relate gas sensitivity to grain size (D) and the geometry of contacts between the SnO_2 particles include the intergrain model and the neck model. An extended approach taking into account both models has been developed by Yamazoe and Miura [34], in which gas sensitivity is related to electron charge transfer within the microstructure of the polycrystalline elements (cf. Fig. 4 B).

Selectivity. The selectivity of all semiconductor gas sensors is very limited, but it can be optimized within narrow limits by choosing the best operating temperature and the most appropriate dopant. As in the case of pellistors, overall selectivity is controlled by the ultimate rate-determining step; i.e., the compound that

shows the highest oxidation rate determines the selectivity. As is generally the case, the slowest step controls the overall reaction rate. In order to construct a sensor that selectively transforms only the analyte into another product, side reactions must be prevented between the compound that is actually detected (here oxygen) and compounds other than the analyte. This is nearly impossible to achieve in the case of a considerable excess of interfering compounds. Since the physicochemical phenomenon underlying heterogeneous catalysis is based on adsorption–desorption steps and subject to the kinetics of the heterogeneous chemical reaction itself, no known mechanism displays exceptional selectivity. It is not generally possible for a solid-state surface to recognize a single class of molecules because the forces involved in the ad- and desorption steps are rather strong, and are influenced only by overall molecular design and not by details of molecular structure, in contrast to the situation with biocatalysts. It must also be kept in mind that every compound can be considered as a potential interferant, since it might influence the heterogeneous rate constant for catalysis even if it does not itself react with oxygen. This also means that every catalyst poison, such as silicones or even dust blocking the active surface, is likely to interfere in a measurement, which in turn limits the possibility of using chemometric methods to correct for errors caused by lack of selectivity.

Humidity effect. Humidity often influences both the zero point of a Taguchi sensor and the sensitivity, which makes corrections difficult as shown in Figure 9.

Table 1 demonstrates that this is the general behavior of semiconductor gas sensors. The slope of the calibration curve can vary by up to a factor of 5. In this table, three different Taguchi sensors (TGS 800, TGS 813, and TGS 822) were carefully compared [257] with respect to their humidity interference using ethanol as the analyte.

This behavior has to be taken into account if these devices are used in electronic noses!

Figure 8. A) Influence of crystallite size (D) on electrical resistance for an SnO_2-based sensor in dry air (R_a) and in air containing 800 ppm H_2 (R_g) at 300 °C (elements sintered at 400 °C); B) Changes in SnO_2 crystallite size as a function of calcination temperature for pure SnO_2 samples and SnO_2 impregnated (5 %) with oxides of various foreign metals [34]
(with permission from Elsevier, Amsterdam)

Figure 9. Effect of the relative air humidity on the response of an SnO_2 semiconductor sensor (Taguchi Type TGS 822) on the calibration cycle with ethanol as analyte. The ethanol concentrations were varied from 13, 26, 65 ppm and the relative humidity between dry, 23 %, 43 %, and 64 % rh.

Table 1. Humidity interference of SnO_2-based gas sensors. Analyte, ethanol; relative humidity rh; S = sensitivity /slope of calibration curve at 12.5 ppm ethanol; norm = factor of sensitivity increase in corresponding humid air (values in parenthesis)

Ethanol, ppm	rh, %	*S*, mV/ppm		
		TGS 800	TGS 813	TGS 822
13	0.00 ± 0.00	14.368 (1.00)	3.568 (1.00)	9.571 (1.00)
26	22.23 ± 0.42	57.752 (4.02)	13.850 (3.88)	47.423 (4.95)
39	42.13 ± 1.18	61.776 (4.30)	15.488 (4.34)	52.851 (5.52)

2.2.3. Selective Ion Conductivities in Solid-State Materials

The lambda probe, based on selective oxygen ion diffusion through solid yttrium-doped ZrO_2 above 400 °C, is an extremely selective sensor for gaseous oxygen. Frequently used for measuring the residual oxygen content in exhaust gases from internal combustion engines, the lambda probe is primarily a potentiometric device that functions as a concentration cell in which gaseous oxygen is in equilibrium with lattice oxygen in the solid electrolyte (Fig. 10). A higher concentration of oxygen on one side of the membrane leads to a potential difference which, according to the Nernst equation, is proportional to the ratio of the two oxygen concentrations. Likewise the fluoride ion-selective electrode based on selective fluoride-ion diffusion through solid-state (crystalline) LaF_3 is an extremely selective sensor for fluoride ions in solution.

Selectivity in both of these cases is controlled by the size and the charge of the diffusing ion. The diffusion process takes place via discrete ion jumps to nonoccupied lattice positions and/or from and to interstitial positions. Ion selection here can be regarded as a filtering process, with the additional requirement for an appropriate ionic charge to prevent overall electroneutrality. Because the analyte molecules and ions involved are rather small, they can be separated quite readily from larger molecules or ions. Thus, the solid-state material functions like an ideal permselective membrane. Any solid state material characterized by exceptionally high ionic conductivity, such as Ag_2S (which has extremely high Ag^+-ion conductivity), will be a very good sensor for that ion. In the case of the ion-selective membrane electrodes used as Nernstian potentiometric sensors in solution, however, more detailed consideration is necessary (see Section 2.3.1.1).

Since the analyte recognition process is here rather straightforward, and because the filtering effect is accompanied by additional restrictions (appropriate charge and multiple straining), the selectivities obtained through this approach to

measuring are extremely high. Many of the compounds that interfere do so not through direct participation in the solid-state diffusion process but rather by affecting the analyte concentration on the sensor surface by other means (e.g., reactions with the analyte, etc.). Thus, with the help of appropriate catalysts and high temperatures the λ-probe can also be used for the detection of other analytes that are oxidized at the surface and thereby reduce the amount of adsorbed oxygen.

2.2.4. Selective Adsorption – Distribution and Supramolecular Chemistry at Interfaces

Supramolecular chemistry has been a source of fascinating new molecular recognition processes. At the active center of a biocatalyst (enzyme) and/or in the binding region of a large antibody macromolecule, the recognition process is attributable mainly to a perfect bimolecular approach of complementary structures. Association or binding occurs only if the relatively weak intermolecular forces involved (dipole – dipole and van der Waals forces) are further supported by a uniquely favorable bimolecular approach that encourages interatomic interactions. A selective reaction of this type requires that the host molecule be carefully tailored so that it matches the guest molecule perfectly. Molecular modeling with attention to the activation energies for closest approach is an especially valuable tool in the design of synthetic host molecules for particular analytes. The analyte can be either a charged or an uncharged species. In the case of an uncharged molecule, however, selective binding of the analyte to the host molecule must be detected with the aid of a mass-sensitive transducer or by following the changes of certain optical parameters.

Further research in the field of supramolecular chemistry for sensors seems warranted given the prospect for improved selectivity based on custom-tailored synthetic guest molecules for the selective binding of particular host molecules (analytes). Even differentiation between enantiomers may be achievable. The latter could be demonstrated by employing known stationary phases used in gas chromatography for the separation of enantiomers also on the surface of mass sensitive transducers. It has been claimed that the technique of molecular imprinting polymers (MIP) is able to perform a similiar high selectivity. While this may be achievable in chromatographic separations due to the high repetition of multiple interface equilibria, it has not yet been convincingly shown for a chemical sensor with a single "hit and recognize" event. The rigidity of the polymer backbone of the imprint makes it highly unlikely that the same recognition power as flexible biomolecules with their "induced-fit" approach can be achieved.

2.2.5. Selective Charge-Transfer Processes at Ion-Selective Electrodes (Potentiometry)

An important aim of quantitative analytical chemistry is the selective detection of specific types of ions in aqueous solution. An electrode capable of selectively detecting one type of ion is called an *ion-selective electrode* (ISE). The operating principle of a particular ISE depends upon the nature of the interaction between ions in solution and the surface of that electrode. Consistent with thermodynamic distribution, the ion in question crosses the phase boundary and interacts with the electrode phase after first discarding its hydrate shell (new studies have shown that this may not always be the case in a quantitative sense, since water can be detected in ion-selective PVC membranes), which results in a net flow of ions across the boundary. Ideally, the counterion would not take part in this flow, so

a charge separation would develop, causing the counterion to remain in the neighboring border area. This is almost the situation when there will be no net energy gain by this transfer due to some supramolecular binding, and a distribution because of the lipophilicity of counterions should be less pronounced. The resulting electrode potential (difference) between the interior of the electrode and the bulk of the sample solution can be described thermodynamically and kinetically – again, in the ideal case – by the Nernst equation.

The selectivity of such a potentiometric device is that of an ideal Nernstian sensor, the potential of which remains stable irrespective of the fact that some current may be flowing through the sensor interface. An ideal Nernstian sensor is characterized by a current – voltage curve that is very steep and nearly parallel to the current axis.

The selectivity of a potentiometric ion-selective interface is controlled largely by interfacial charge-transfer kinetics and not by the stability constant for reaction of the analyte ion with the electroactive compound (e.g., valinomycin in the case of potassium ion). The exchange-current density for the analyte ion relative to interfering ions determines the extent of potentiometric selectivity. Any factor that increases the former (conditioning of the electrode with the measuring ion, ion-pair formation by lipophilic counterions, etc.) leads to a better and more selective Nernstian sensor. The ideal electroactive compound apparently behaves like a selective charge-transfer catalyst for the analyte ion. Advantages that might perhaps be gained from tailored host molecules for accelerating the transfer of analyte ions into the surface of the electrode have not yet been fully investigated. Recognition of an analyte ion depends upon size and charge as well as the speed with which the ion loses its solvent sphere prior to entering the electrode phase. Therefore, the electroactive compounds most suitable for embedding in the membrane of an ion-selective electrode (usually consisting of PVC containing a plasticizer) are those that play an active role in successive replacement of the often firmly held hydrate shells of the analyte ions. Results clearly demonstrate that the thermodynamic complex stability constants determined in homogeneous solution (e.g. via NMR) do not mirror the potentiometric selectivity! A newly synthesized compound for sodium ions, as an example, turned out to yield a very selective PVC membrane for $Pb(OH)^+$ ions [40]. While in theory supramolecular recognition worked perfectly well in homogeneous solutions, at the interface a different mechanism obviously plays a dominant role.

2.2.6. Selective Electrochemical Reactions at Working Electrodes (Voltammetry and Amperometry)

Depending on the potential range at the working electrode, as many as about ten different electrode processes can be separated voltammetrically based on the typical resolution of a polarographic curve, which requires a difference voltage of about 200 mV for the half-wave potential and a concentration-dependent limiting current. Selectivity in the process is therefore rather limited, and depends on such thermodynamic parameters as the reaction enthalpy for reduction or oxidation at the electrode surface. The potential of the working electrode determines whether a particular compound (analyte) can be oxidized or reduced, and compounds with similar redox characteristics might interfere.

The problem of interference is of course greatest when extremely positive or negative working electrode potentials are applied at the working electrode, since at high potential the small differences between electrochemical reaction rates become negligible. The "resolution" of a typical current – voltage curve is diminished if the electrochemical reaction is kinetically hindered, resulting in so- called irreversible current steps that are less steep. Irreversible electroactive species require a greater overpotential before the diffusion- controlled limiting current plateau is reached, therefore increasing the chance that an interfering compound will become electrochemically active. The limited resolution power of voltammetry can be improved by the use of chemically modified electrode surfaces. If a surface layer or a thin membrane is introduced between the phase boundary this additional layer will increase the selectivity if only the analyte can pass through this layer.

In certain biosensors an irreversible heterogeneous reaction is transformed into a homogeneous redox reaction via a very reversible redox

system. The latter can be transformed back at the working electrode by a much lower overpotential, thereby reducing the chance of co-oxidation or co-reduction of interfering compounds. Since the limiting current is strictly proportional to the analyte concentration and also to the concentrations of interfering compounds, chemometric data treatment and/or differential measurements may be used to correct for errors.

2.2.7. Molecular Recognition Processes Based on Molecular Biological Principles

Metabolic biosensors are based on special enzyme- catalyzed reactions of the analyte. The recognition process, also known as the lock-and-key principle, is extremely selective, permitting differentiation even between chiral isomers of a molecule. Recognition in this case demands a perfect geometrical fit as well as the appropriate dipole and/or charge distribution to permit binding of the analyte molecule inside the generally much larger biomolecule (host). Since fitting is associated with all three dimensions, a very large biomolecule with its stabilized structure is more effective than the smaller host molecules commonly encountered in supramolecular chemistry. The selectivity of a specific biocatalytic reaction can be further improved by ensuring detection of only the transformed analyte or a stoichiometric partner molecule through a chemical transducer located behind the recognition layer. In a certain sense, this type of biosensor represents the highest possible level of selectivity, and comparable results would be difficult to achieve by other means.

Immunosensors based on mono- or polyclonal antibodies constitute the second best choice with respect to high selectivity. Depending on the amount of effort expended in screening and choosing the desired antibodies from among the millions of different antibody molecules available, the selectivity can be remarkably high. On the other hand, it is also possible to choose antibody molecules that bind only to a certain region (epitope) of the analyte molecule, leading to biomolecules capable of recognizing all members of some class of compounds sharing similar molecular structures. This type of sensor, though it cannot be calibrated, is very valuable for screening purposes used to detect the presence of an only certain class of substance . The application of antibody molecules has been considerably simplified by the large-scale preparation of monoclonal versions with precisely identical features. It has even become possible to construct immunosensor arrays based on monoclonal antibody molecules with exactly matched selectivities. Results obtained from such arrays must be evaluated by modern methods of pattern recognition.

In order to overcome the limited stability of large protein molecules, research aims isolate only the binding region of the F_{ab} part (antibody-binding fragment) of an antibody molecule. Smaller molecules are of course likely to display somewhat more limited recognition ability, however, with selectivities approaching those of supramolecular host molecules synthesized in the traditional way. Research has also focussed on recombinant antibodies produced from large protein libraries without the need for any animal immunization.

2.3. Transducers for Molecular Recognition: Processes and Sensitivities

2.3.1. Electrochemical Sensors

Electrochemical sensors constitute the largest and oldest group of chemical sensors. Although many such devices have reached commercial maturity, others remain in various stages of development. Electrochemical sensors will be discussed here within the broadest possible framework, with electrochemistry interpreted simply as any interaction involving both electricity and chemistry. Sensors as diverse as enzyme electrodes, high-temperature oxide sensors, fuel cells, and surface- conductivity sensors will be included. Such sensors can be subdivided based on their mode of operation into three categories: *potentiometric* (measurement of voltage), *amperometric* (measurement of current), and *conductometric* (measurement of conductivity) [13], [41].

Electrochemistry implies the transfer of charge from an electrode to some other phase, which may be a solid or a liquid. During this process chemical changes take place at the electrodes, and charge is conducted through the

bulk of the sample phase. Both the electrode reactions themselves and/or the charge transport phenomenon can be modulated chemically to serve as the basis for a sensing process. Certain basic rules apply to all electrochemical sensors, the cardinal one being the requirement of a closed electrical circuit. This means that an electrochemical cell must consist of at least two electrodes, which can be regarded from a purely electrical point of view as a sensor electrode and a signal return.

Another important general characteristic of electrochemical sensors is that charge transport within the transducer portion of the sensor and/or inside the supporting instrumentation (which constitutes part of the overall circuit) is always electronic. On the other hand, charge transport in the sample under investigation may be electronic, ionic, or mixed. In the latter two cases electron transfer takes place at the electrode – sample interface, perhaps accompanied by electrolysis, and the corresponding mechanism becomes one of the most critical aspects of sensor performance.

The overall current – voltage relationship is complex, and it can vary as the conditions change. The relationship is affected primarily by the nature and concentration of the electroactive species, the electrode material, and the mode of mass transport. A total observed current can be analyzed in terms of its cathodic and anodic components. If the two currents are equal in magnitude but opposite in sign, there must be an *exchange current* passing through the electrode-surface/sample interface.

Both the charge-transfer resistance and the exchange-current density are critically important parameters in the operation of most electrochemical sensors, since they reflect the kinetics of an electrode reaction. These parameters are directly proportional to the electrode area, so the smaller the electrode the higher will be the resistance, all other parameters remaining unchanged. Therefore, it is the electrochemical process taking place at the smaller electrode that determines the absolute value of the current flowing through the entire circuit. The auxiliary electrode will begin to interfere only if its charge-transfer resistance becomes comparable to that of the working electrode. Microelectrodes represent one approach to avoiding such interferences (see Section 2.3.1.2).

On the other hand, in zero-current potentiometry the relative sizes of the two electrodes is immaterial. Acquiring useful information in this case requires only that the potential of the working electrode be measured against a well-defined and stable potential from a reference electrode. Any foreign potential inadvertently present within the measuring circuit can contaminate the information, so it is mandatory that the reference electrode be placed as close to the working electrode as is practically possible. Thus, in an amperometric (or conductometric) measurement the source of information can be localized by choosing a small working electrode, whereas it cannot be localized with zero-current potentiometric measurements.

2.3.1.1. Self-Indicating Potentiometric Electrodes

Fundamental Considerations. Within the context of this chapter "potentiometry" is understood to mean the measurement of potential differences across an indicator electrode and a reference electrode under conditions of zero net electrical current. Such a measurement can be used either for determining an analyte ion directly (direct potentiometry) or for monitoring a titration (see below).

Potentiometry has proven to be well suited to the routine analysis of a great number and variety of analytes [5], [40], [42–60]. Ion-selective electrodes (ISEs) are commercially available for many anions and cations, as indicated in Tables 4, 5, 6, 7. Other analytes can be determined using ISEs in an indirect way. Chapter 3 deals with various types of potentiometric biosensors. A special advantage of ion-selective potentiometry is the possibility of carrying out measurements even in microliter volumes without any loss of analyte.

At present, most ISEs unfortunately do not provide absolute selectivity for a single ion. This fact requires that one have access to very detailed information regarding the nature of samples to be analyzed so that interferences can be either eliminated or otherwise taken into account.

The theory of (ion-selective) potentiometry has already been introduced in Section 2.2.5. Here it is necessary only to remind the reader of the Nernst equation and the Nernst – Nikolsky equation, both of which are

used in the evaluation of potentiometric measurements.

The *Nernst equation* is valid only under ideal conditions (with no interfering ions, etc.):

$$E = E^0 + (RT/zF)\ \ln a_{\mathrm{M}} \tag{5a}$$

$$= E^0 + (0.059/z)\ \log a_{\mathrm{M}} \tag{5b}$$

The *Nernst–Nikolsky equation* on the other hand takes into consideration the influence of interfering ions on the potential of an ISE:

$$E = E^0 + (RT/z_{\mathrm{M}}F)\ \ln\left[a_{\mathrm{M}} + \sum K_{\mathrm{MI}}\,(a_{\mathrm{I}})^{z_{\mathrm{M}}/z_{\mathrm{I}}}\right] \tag{6}$$

where

E = potential of the ISE, measured with zero net current
E^0 = standard potential of the ISE
R = gas constant (8.314 J K^{-1} mol^{-1})
T = absolute temperature (K)
F = faraday constant (96 485 C/mol)
a_{M} = activity of the ion to be measured
a_{I} = activity of an interfering ion
$z_{\mathrm{M}}, z_{\mathrm{I}}$ = electrical charges of the measured and interfering ions
K_{MI} = selectivity coefficient

The value of K_{MI} depends both on the activity a_{M} and on the particular combination of analyte ion and interfering ion. Bakker [48] suggested another equation which described the EMF versus concentration behavior of an ISE with a higher accuracy. The selectivity coefficients are determined here without conditioning the electrode with the measured ion, which yields constant selectivity coefficients. The new equation describes the situation when a monovalent analyte ion I^+ is interfered by a divalent ion J^{2+} especially well, and *vice versa*:

$$E = E_{\mathrm{I}}^0 + \frac{RT}{F}\ \ln\left(\frac{a_{\mathrm{I}}\,(\mathrm{IJ})}{2} + \frac{1}{2}\sqrt{a_{\mathrm{I}}\,(\mathrm{IJ})^2 + 4a_{\mathrm{J}}\,(\mathrm{IJ})\left(K_{\mathrm{IJ}}^{\mathrm{pot}}\right)^2}\right) \tag{6a}$$

for $z_{\mathrm{I}} = 2$ and $z_{\mathrm{J}} = 1$

$$E = E_{\mathrm{I}}^0 + \frac{RT}{F}\ \ln\left(\sqrt{a_{\mathrm{I}}\,(\mathrm{IJ}) + \frac{1}{4}K_{\mathrm{IJ}}^{\mathrm{pot}}a_{\mathrm{I}}\,(\mathrm{IJ})^2} + \sqrt{\frac{1}{4}K_{\mathrm{IJ}}^{\mathrm{pot}}a_{\mathrm{I}}\,(\mathrm{IJ})^2}\right) \tag{6b}$$

Horvai [49] developed another more general equation for ion-selective ion-exchange membranes, which also considers the concentration dependency of the selectivity coefficient:

$$E \cong E_{\mathrm{I}}^0 + \frac{RT}{z_1F}\ln a_1\,(\mathrm{IJ}) + \frac{RT}{z_1F}K_{\mathrm{IJ}}a_{\mathrm{I}}\,(\mathrm{IJ})^{z_{\mathrm{J}}/z_{\mathrm{I}}}\,a_{\mathrm{J}}\,(\mathrm{IJ}) \tag{6c}$$

One can see here, separated from each other, the response of the ISE towards the pure analyte ion I and (as the last term) the EMF deviation caused by the interfering Ion J. Note that there is no logarithm in the last term and also that the last term depends both on the interfering and primary ion concentrations.

Types of Ion-Selective Electrodes. Simple metal-ion electrodes such as those based on silver, gold, platinum, etc., will not be dealt with in this discussion since they are used mainly for indicating purposes in potentiometric titrations. Apart from these, the following types of ISEs can be distinguished:

1) Glass-membrane electrodes
2) Solid-membrane electrodes
3) Liquid-membrane electrodes (including PVC membrane electrodes)
4) ISEs based on semiconductors (ion-selective field-effect transistors, etc.)

These four types will be the subject of more detailed consideration.

Glass-Membrane Electrodes [50]. The best-known glass-membrane electrode is the pH electrode. Its most important component is a thin glass membrane made from a sodium-rich type of glass. Depending on the intended application the membrane may take one of several geometric forms: spherical, conical, or flat. For applications in process streams, special pH electrodes have been devised that are resistant to high pressures, and sterilizable pH electrodes are available for biotechnological applications.

Examples of the different types of pH electrodes are illustrated in Figure 11. The *spherical* type is most frequently used for the direct measurement of pH or for acid–base monitoring. It is robust and appropriate for most routine applications. *Conical* electrodes can be used as "stick-in electrodes" for pH measurements in

meat, bread, cheese, etc. A conical membrane can easily be cleaned, which is important if measurements are to be made in highly viscous or turbid media. A *flat* membrane facilitates pH measurements on surfaces, such as on human skin.

Figure 11. Various types of glass-membrane pH electrodes (with permission from Springer-Verlag, Heidelberg)
A) Spherical membrane; B) Conical membrane; C) Flat membrane
a) Fill hole; b) Inner filling solution (buffer); c) Reference system

The pH electrode must be combined with a reference electrode [51] that provides a constant potential for completing the electrical circuit. A suitable reference system is frequently integrated into the body of the pH electrode itself. Combined electrodes of this type are particularly easy to handle. pH Measurements at > pH 10 by means of glass electrodes are subject to interference by alkalimetal ions, especially Na^+. The selectivity coefficient K_{MI} for interference by the sodium ion is 10^{-13} in special lithium containing glasses with a reduced alkali error. This means that a 10^{13}-fold concentration of sodium is required to produce the same potential as a given concentration of protons.

It is important that the surface of a glass membrane be swollen before measurements are taken. Prior to first use the electrode should therefore be allowed to swell overnight in a 3 mol/L KCl solution. For the same reason the electrodes should also be stored in a solution of this type between measurements and after measurements have been conducted in nonaqueous solvents. Here, the choice of a double junction reference electrode with the same solvent as in the measuring solution and added organic salt for sufficient conductivity is important. In the case of endpoint detection a platinum/ferrocene redox element without a liquid junction could also be used.

Apart from the pH-selective glass-membrane electrodes, other commercially available glass-membrane electrodes are responsive to sodium ions, although the selectivity of a pNa electrode is much lower than that of a pH electrode. Approximate selectivity coefficients K_{MI} in this case are 10^3 for interference by H^+ and 10^{-3} for interference by Li^+, K^+, and Cs^+. However, an interference by H^+ ions is seldom serious since by appropriate pH adjustment one can easily shift the H^+ ion concentration to a range where it does not influence the electrode potential.

Solid-Membrane Electrodes. The sensing element of a solid-membrane electrode consists of a material showing ionic conductivity for the particular ions that are to be determined. Such a device may be manufactured from a single crystal, as in the well-known fluoride-selective electrode, where the sensing element is a single crystal of lanthanum fluoride doped with europium(II) fluoride to lower the electrical resistance. Alternatively, a membrane can be produced by grinding the crystalline sensor material together with an appropriate additive (PTFE powder, silicone rubber), followed by solidification either by application of high pressure or by addition of a cross-linking agent. It is thus essential that the crystal particles stay in contact which each other. In addition to these so-called heterogeneous membranes, the homogeneous membranes based on silver sulfide are better known. They consist of Ag_2S which is freshly precipitated, washed, dried, and pressed into a pellet with a traditional KBr-IR press. Since Ag_2S is rarely stoichiometric it shows a high Ag^+ ion conductivity leading to a perfect Nernstian-sensor for that ion. Because the standard exchange current density at its suface is much higher than on a silver metal surface (overpotential due to crystallization polarization) it senses lower Ag^+ ion concentrations much better. By incorporating about 30 weight % of a certain silver halide into this pellet one obtains the corresponding halide sensitive membrane. Note, the same result would be obtained if the appro-

priate silver halide were to be added as a powder to the measuring solution. That means that it is still the Ag^+ ion which determines the potential via the corresponding solubility product. If certain metal sulfides such as CuS, PbS, or CdS are added the membrane senses those metal ions via two solubility products and an intermediate S^{2-} ion-concentration. Thus, Ag^+ ions must be totally absent as well as compounds oxidize S^{2-}.

The membrane is then fixed to the electrode body. Electrical contact is established either by a conducting adhesive or by an internal reference system. Figure 12 illustrates schematically the construction of two types of solid-membrane electrodes. A detailed compilation of commercially available solid-state electrodes is provided in Tables 4, 5, 6, 7 at the end of this section.

Figure 12. Two types of solid-membrane electrodes (with permission from Springer-Verlag, Heidelberg)
A) With internal filling solution and reference system; B) With solid contact

Generally speaking, interference must be anticipated from any ion that tends to react with the membrane material to form compounds less soluble than the membrane itself. Thus, the chloride electrode, which consists of a $AgCl/Ag_2S$ membrane, is poisoned by mercury(II) ions. Due to the solid state of the membrane the reaction rate is rather low, so a poisoned membrane can be repaired by carefully polishing it with an appropriate polishing powder (as described in instruction manuals furnished with the electrodes).

Liquid-Membrane Electrodes. The electroactive phase in this type of electrode consists of a liquid that has been stabilized mechanically. For this purpose the electroactive components may be dissolved in a highly viscous and apolar organic solvent such as one of the higher alcohols or paraffin. A porous material (e.g., commercial membrane filters such as Sartorius cellulose nitrate with pore diameters of about 0.45 µm), are initially made hydrophobic with, e.g., hexamethyl disilazane and then soaked with this solution and introduced in place of the solid membrane in an electrode of the type described above. More frequently, however, the liquid is not fixed in a porous material, but rather embedded into a high molecular mass polymer like PVC. In this case the plasticizer (normally present at a concentration of about 66 % by weight) acts as a solvent for the electroactive component (the concentration, which seldom exceeds 1 %!). Simplified construction schemes for these two types of electrodes are illustrated in Figure 13.

Figure 13. Two types of liquid-membrane electrodes (with permission from Springer-Verlag, Heidelberg)
A) Porous-membrane electrode; B) PVC-membrane electrode
a) Reservoir for liquid ion carrier; b) Porous membrane; c) Reference system; d) PVC membrane; e) Reference system

For applications like those discussed in Sections 2.2.4 and 2.2.5 the electroactive component of a liquid-membrane electrode would consist of a (charged) ion exchanger or an (uncharged) ion carrier. In both cases the electroactive component must have a rather high affinity for the ion to be determined, but at the same time display the greatest possible selectivity with respect to interfering ions. Table 2 lists ion exchangers and ion carriers frequently used in liquid-membrane ISEs. For an excellent and almost exhaustive compilation of ISEs based

on this principle see the reviews of BAKKER, BÜHLMANN, and PRETSCH [59], [60].

Table 2. Example of ion exchangers and ion carriers frequently encountered in liquid-membrane electrodes

Ion	Electroactive compound
Cations	
K^+	valinomycine
NH_4^+	nonactine – monactine
Li^+	lithium carrier, e.g., ETH 1644 (Fluka)
Ca^{2+}	calcium salt of didecylphosphonic acid
Anions	
NO_3^-	Ni(*o*-phen)$_3^{2+}$
ClO_4^-	Fe(*o*-phen)$_3^{2+}$
BF_4^-	Fe(*o*-phen)$_3^{2+}$

The first part of these publications deals with the most recent theoretical treatment while the second part describes in detail nearly all known membrane compositions for nearly every ion of particular importance. It should be noted that PVC-based ISEs are especially easy to construct in the laboratory just before they are to be used. The Fluka company offers a large collection of electroactive compounds (including the most famous ones with their characteristic ETH number), the right PVC and plasticizer and also construction information. Recently reasons for the typical detection limits in the range of μM solutions have been found [61]. If the internal filling solution contains too high a concentration of the measured ion it will be distributed through the entire membrane and can be exchanged with interfering ions at the measuring surface and thereby produce a certain concentration in the sample solution. Thus, in case of trace determinations the inner concentration of the measured ion should be $<$ μM. However, care is needed not to loose the internal measured ion by adsorption processes. Thus, an appropriate ion-buffer leading to a constant low concentration is recommended.

For anion determinations, most PVC-membrane based ISEs follow the so-called Hofmeister series, which is: the more lipophilic anion is always more favored by the organic membrane and therefore sensed better. However, there are exceptions to this general rule which are also most interesting from a theoretical point of view, especially when a supramolecular carrier is used and more than the typical one lipophilic salt addition is performed. Because of this, owing to the incorporation of a lipophilic cation and anion, a carbonate selective ISE could be constructed with decreased interference from salicylate by five orders of magnitude [62]. This addition surprisingly increases the charge transfer resistance of the ISE so that it can be measured besides the high bulk resistance in series. However, the ratio of the transfer resistances for the analyte and the interfering ions changes too, in favor of the measured ion!

ISEs Based On Semiconductors (*ISFETs*). Devices based on ion-selective field-effect transistors (ISFETs) are sufficiently distinctive to warrant separate treatment in Section 2.3.1.4.

Instrumentation. The discussion here of instrumentation required for potentiometric measurements will be limited to a brief overview of suitable reference electrodes [51]. The conventional reference electrode consists of an electrode of the second kind, like the Ag/AgCl/KCl system. Much effort has been devoted to the development of miniaturized reference systems suited to direct integration into ISFETs, but most systems of this type fail to fulfill all the requirements for a "true" reference electrode with a well-defined and stable potential difference relative to the standard hydrogen electrode. The greatest problem is the short distances needed for the liquid junction, leading to an influx of unwanted compounds within too short a time period. Reference electrodes with gel-stabilized internal electrolytes are produced for applications in process analysis.

Table 3 provides an overview of the most frequently used reference electrodes.

Evaluation of Potentiometric Results. The aim of all methods for the evaluation of potentiometric data is the computation of substrate activities from voltage changes observed between an ISE and a reference electrode. Generally speaking, three different approaches are possible: (1) the direct potentiometric measurement of activities, (2) monitoring during the course of a titration, and (3) flow-injection analysis (FIA).

A determination by *direct potentiometric measurement* is accomplished either by calibrating the electrode with solutions of known concentration, or by using the techniques of standard addition or standard subtraction. Since calibration with standard solutions usually in-

Table 3. Common reference electrodes

Electrode	Potential vs. NHE	Useful temperature range, °C	Interferences
$Hg/Hg_2Cl_2/KCl$ (0.1 mol/L)	+0.334 V		
$Hg/Hg_2Cl_2/KCl$ (1.0 mol/L)	+0.280 V	15 – 70	complexing agents (CN^-), S^{2-}, strong oxidizing or reducing agents

Tl(Hg)/TlCl/KCl (3.5 mol/L)	− 0.575 V	15 – 120	S^{2-}, strong oxidizing agents; no interference from complexing agents

volves solutions of pure salts, thorough knowledge of the samples to be analyzed is a prerequisite to avoiding erroneous results due to interfering ions present in the sample matrix. Influences attributable to other substances present in the sample that do not interfere directly with the determination but produce changes in ionic strength can be minimized by adding a total ionic strength adjusting buffer ("TISAB solution") to both standard solutions and samples. Standard-addition or -subtraction methods should be invoked whenever it is not possible to make appropriate standard solutions (owing to a very complex matrix, for example). Figure 14 illustrates the evaluation of a standard-addition analysis.

Monitoring a titration by means of an ISE has the advantage over direct potentiometric measurement that the accuracy is determined largely by the titration reaction and not simply by the calibration function of the electrode. This is especially important for ISEs with changing or unknown slopes. For this reason the determination of a surfactant should always be carried out as a titration and not as a direct measurement.

Flow-Injection Analyses with ISEs are especially easy to carry out. If the ISE has a flat surface it can be connected to the liquid junction of a reference electrode via a small strip of filter paper. This paper strip is then held by a clamp and the carrier stream of the FIA system is applied just before the measuring ISE, passing over its surface and later over the reference electrode. New levels of ultra trace analysis can be reached – as already mentioned – by never conditioning the ISE membrane with higher concentrations of the measured ion either from the outside or from the inside! This automatically leads to a differential FIA operating mode in which the injected sample segment is first passed over one of the ISE surfaces and then with a matched retarding coil to the other side of the ISE membrane. Figure 15 shows results and the experimental set-up with two external reference electrodes, the ISE membrane and the redarding coil which should direct the sample segment to the second site of the ISE-membrane exactly at the moment it leaves the first side [63]. In ultra trace analysis the carrier solution should contain only traces of the measured ion in order to get a stable voltage reading. Note that the injection volume in Figure 15 is in the µL range. Thus, such a simple and low cost approach allows the determination of pg amounts as it is demonstrated in Figure 16.

Commercially Available ISEs. Tables 4, 5, 6, 7 provide an overview of ISEs commercially available at the time. ISEs described only in the literature, and which must therefore be selfconstructed, have not been included in the tables. Instructions for the preparation of PVC-membrane elecrodes can be found in the literature [4], [5], [15].

Table 4. Commercially available ISEs with selectivity for cations

Figure 14. Plot for the evaluation of a standard-addition analysis
V_S = Volume of standard solution; V_x = Volume of analyte
$\Gamma = pE \cdot V_{total}$, with $pE = 10^{\Delta E.(z/S)}$ (ΔE = Potential difference; z = Charge of the ion, including sign; S = Slope of the electrode, including sign)
The unknown concentration of the analyte c_x is $c_x = (-c_s \cdot V_x)/V_{initial}$, where c_s = Concentration of the standard solution and $V_{initial}$ = Initial volume of the analyte

Figure 15. Differential flow-injection analysis with one single ISE membrane and two reference electrodes in an electrolytic closed loop.
An injector block used in liquid chromatography injects about 500 µL of sample into the carrier stream. The volume of the carrier stream loop from one side of the ISE membrane to the opposite side including the volume of both membrane sides is also approximately 500 µL. Thus, when the sample segment is fully washed out of the first membrane side the first front of it reaches the backside. Through this a positive and a negative analyte peak are obtained, which look like a second derivative of a peak.
C = carrier solution; S = sample (introduction with injector loop); P = pump; L = loop adapted to different sample volumes; D = detector; M = ISE membrane with two spacers with a flow channel on each side; Ref I and Ref II = commercial reference electrodes with threads

Table 7. Commercially available ISEs with selectivity for miscellaneous species

ISE type	MT [a]	Concentration range, mol/L [b]	Useful pH range [b]	Temp. range, °C [b]	Membrane resistance, MΩ [b,c]	Suppliers [d]	Interfering ions [b,e] in order of decreasing interference; miscellaneous remarks
Hard [f]	P	$7 \cdot 10^{-6}$–1		0–50		O	not sorted: Na^+, Cu^{2+}, Zn^{2+}, Fe^{2+}, Ni^{2+}, Sr^{2+}, Ba^{2+}, K^+ oppositely charged bulky ions interfere with the titration reaction; high concentrations of nonionic surfactants may interfere
Surf [g]	P	$\approx 10^{-6}$; [h]	1–13	0–40		MO	

[a] MT = Membrane type; G = Glass-membrane electrode; P = PVC-membrane electrode; S = Solid-state membrane electrode; M = gas-permeable membrane electrode. Glass and solid-state membranes are more resistant to certain organic solvents (acetone, methanol, benzene, dioxane, etc.). PVC-membrane electrodes must not be allowed to come into contact with any organic solvent, because this dramatically reduces the lifetime of the electrode.
[b] Mean values as provided by the suppliers.
[c] Only if different suppliers provide very different values for membrane electrical resistance are two values listed in the table.
[d] This list was compiled in Spring 1993 and should not be regarded as complete; C = Ciba Corning; I = Ingold Messtechnik; M = Metrohm; O = Orion; R = Radiometer; W = WTW; Ω = Omega.
[e] A very detailed compilation of selectivity coefficients is available in [23].
[f] Hard: water hardness; i.e., divalent cations.
[g] Surf = ionic surfactants.
[h] This type of ISE should be used only for the monitoring of titrations; the value cited refers to the miminum titratable concentration of an anionic surfactant (pure solution).

2.3.1.2. Voltammetric and Amperometric Cells

Information is obtained with this type of electrochemical sensor from either the combined current/potential – concentration relationship (voltammetry) or from the current – concentration relationship alone (amperometry).

A voltammetric measurement is accomplished by scanning the potential difference across an electrochemical cell containing a working electrode, a reference electrode and usually an auxiliary electrode separated from the sample solution with a diaphragma from one preset value to another and recording the cell current as a function of the applied potential. A curve so generated is known as a *voltammogram.* Amperometric measurements are made by recording the current flow in a cell at a single applied potential.

The essential operational function of a transducer for this purpose is the transfer of one or more electrons to or from the transducer surface (= working electrode). The flow of these electrons is what constitutes the output signal. Voltammetric and amperometric devices are also capable of conferring a degree of selectivity on the overall sensing process by the proper choice of the working electrode potential against a reference electrode.

Furthermore they are relatively simple: in the most elementary case, the transducer (electrochemical cell) consists of nothing more than two electrodes immersed in a suitable electrolyte. A more complex arrangement might involve the use of a three-electrode cell mentioned above, with the advantages that the reference half-cell is not disturbed (polarized) by the current flowing and that the *ixR* drop can be compensated by such a set-up.

In spite of the inherent diagnostic advantages of voltammetry, a transducer based on this technique represents a rather cumbersome approach to sensing, mainly because of the electronic circuitry required to scan the applied potential, the time needed for a single scan, and the evaluation algorithm identifying the correct current peak to be measured. Accordingly, most sensing applications involve cells operating in an amperometric (fixed potential) mode.

Figure 16. The calibration plot in the lower ppb range shown was constructed with peak-to-peak values resulting in a double Nernstian response. Because of the FIA detection the ISE membrane is never equilibrated with higher concentrations of the analyte ion.
Details: nitrate-selesctive ISE membrane: 1 % Tetradodecylammoniumbromide; 50 mol % of the first is potassium-tetrakis-(4-chlorophenyl)-borat; 49 % 2-.NPOE; 50 % PVC
Carrier solution: 10^{-3} M $Li_2SO_4 + 10^{-7}$ (!) M KNO_3

Voltammetry. When a slowly changing potential is applied to an electrode immersed in an electrolyte solution containing a redox species, a current will be observed to flow as soon as the applied potential reaches a certain value. This current arises from a heterogeneous electron transfer between the electrode and the redox couple, resulting in either oxidation or reduction of the electroactive species. At a sufficiently oxidizing or reducing overpotential the magnitude of the current may become a function of mass transfer of the redox species to the electrode. In a well-stirred solution so-called quasi-stationary current – voltage curves with typical current steps and plateaus are obtained. The half-step (wave) potential is characteristic of the type of species being electrochemically oxidized or reduced, the height of the current steps represents the concentration of it. Without stirring, current peaks are obtained, since the diffusion towards the working electrode surface is no longer sufficient to maintain a constant current. Redox couples that give rise to symmetrical current peaks separated by $58/z$ mV (at 25 °C) with cyclic voltage ramps in unstirred solutions are frequently referred to as *reversible couples.* If the rate of electron transfer between the redox couple and the electrode is high compared with the rate of mass transfer, then the electrode reaction is reversible. Under these circumstances the concentration ratio for oxidized and reduced forms of the couple at the electrode surface is described by the Nernst equation [Equations (5a) and (5b)].

If electron transfer between the redox species and electrode is very slow (kinetical controlled) relative to the mass transport of solution species to the electrode, then the observed current will not be a function of mass transport. In this case, the low rate of electron transfer results in a concentration ratio of the two forms of the redox couple at the electrode surface that no longer conforms to the Nernst equation. Current – voltage curves of these so- called irreversible processes show the corresponding current peaks more to be separated and of different heights and are of limited analytical utility.

An intermediate situation arises when the electron-transfer and mass-transport rates are comparable. Such quasi-reversible electrode reactions are quite common, and their analytical utility depends to a large extent on careful control of the mass-transfer rate in the electroanalytical method used for their study.

Instruments suitable for voltammetry and amperometry consist of three basic components: a wave-form generator, some form of potential control, and an electrochemical cell. Mod-

ern electroanalytical systems employ a three-electrode arrangement for the electrochemical cell. A device called a *potentiostat* is used to maintain a programmed or fixed potential difference between the two current- carrying electrodes (the working electrode and the auxiliary electrode) relative to a third electrode (reference electrode), the function of which is to provide a fixed potential reference in the cell [64], [65].

Both potentiostats and waveform generators have benefited substantially from the introduction of operational amplifiers, as well as from the availability of desktop computers. Electrochemical cell design is now wellestablished both for static systems and for detectors situated in flowing reagent streams.

Despite the fact that solid electrodes have been in use for electroanalytical purposes for some time and are well documented, selection of an appropriate electrode material and its preparation before use remains an area of considerable interest and great controversy among electroanalytical chemists [66]. Solid electrodes for analytical use should always be prepared in a rigorous and reproducible manner. This generally involves polishing the electrode physically with successively finer grades of carborundum or diamond paste. The polished electrode should then be rinsed thoroughly to remove as completely as possible all traces of the polishing materials.

Many different applied potential waveforms have been employed for analytical purposes, but only a few are of mainstream significance [67], [68]. These are presented in Table 8.

In *linear-sweep* voltammetry the current is recorded while the potential of the working electrode is swept from one selected limit to another at a rate between 1 mV/s and 1000 mV/s. In *cyclic* voltammetry, two linear sweeps are recorded, as shown in Table 8. The distinguishing feature of cyclic voltammetry is that electrogenerated species formed in the forward sweep are subject to the reverse electrochemical reaction in the return sweep [69]. Figure 17 shows a typical cyclic voltammetric curve together with the important parameters. In both methods, as the potential is swept to the electroactive region of the redox couple, the current response rises to a peak value before decaying. This decay is caused by depletion of the electroactive species in the zone close to the electrode surface, which means that the diffusion zone spreads out further into the bulk solution.

Figure 17. Typical potential vs. current (E vs. i) curve from a cyclic voltammetric experiment with a reversible redox couple
A) Starting potential; B) Reverse potential
E^0 = Standard potential; E_{pa} = Anodic peak potential; E_{pc} = Cathodic peak potential; $E_{pa/2}$ = Anodic half-wave potential; $E_{pc/2}$ = Cathodic half-wave potential; i_{pc} = Cathodic peak current; i_{pa} = Anodic peak current

Pulse and square-wave voltammetry [70] are much better candidates for incorporation into a chemical sensor than linear-sweep or cyclic voltammetry, primarily because of the possibility of discriminating between faradaic and capacitive currents. When a potential pulse is applied to an electrode, the capacitive current that flows is proportional to the magnitude of the pulse, and it decays exponentially with time. The faradaic current, on the other hand, decays according to the square root of time. Figure 18 illustrates the expected decreases in faradaic and capacitive currents, showing that the capacitive current decreases faster than the faradaic one. This gives the opportunity of sampling the current only after the capacitive one can be neglected.

Proper selection of the measuring time permits a signal-to-noise ratio to be improved dramatically. This characteristic is exploited in normal-pulse, differential-pulse, and square-wave voltammetry. In the first of these techniques it represents the only mechanism for decreasing the effect of capacitive current. Further elimination of the capacitive current can be achieved in differential-pulse voltammetry by limiting the duration of the applied pulse and

Table 8. Voltammetric techniques (adapted from [26]); $* \rightarrow$ = Point at which the current is measured; τ = Portion of the staircase during which pulses of width $\tau/2$ are superimposed; E_{sw} = Square-wave amplitude.

Technique	Applied potential*	Measured signal	Comments
Linear-sweep voltammetry			used mainly for diagnostic purposes; current measured throughout the scan
Cyclic voltammetry			reversal of the potential at the end of the forward scan makes this a powerful diagnostic tool; current is measured throughout the scan
Differential-pulse voltammetry			the displayed signal is the difference between the current just prior to and at the end of the applied pulse; low scan rates, but good limits of detection
Square-wave voltammetry			the displayed signal is the difference between currents measured on the forward and reverse pulses; rapid scans and good detection limits

by subtracting the current observed immediately prior to the imposition of the pulse. Increased rejection of the charging current leads to improved detection limits; indeed, this variant of voltammetry permits concentrations as low as $10^{-8} - 10^{-7}$ mol/L to be measured quite readily. In order to avoid problems associated with the electroactive species, the delay between application of successive pulses must be approximately one-half second. This in turn imposes a limit on the scan rate in differential-pulse voltammetry, thereby decreasing its usefulness in sensor applications.

The technique of square-wave voltammetry offers greater promise as a voltammetric method for probing selective chemistry because of the high rate at which the corresponding scan can be executed. The analytical signal in this technique constitutes a difference between the current for the forward pulse and the current for the reverse pulse. Because of the large amplitude of the square wave in a reversible reduction, a reduced electroactive species formed at the electrode during the forward pulse is reoxidized by the reverse pulse. Consequently, the sensitivity of the method is enhanced relative to differential-pulse voltammetry.

This element of speed is crucial to square-wave voltammetry, because, like all voltammetric techniques based on pulse waveforms, the measured current is proportional to $t^{-1/2}$. However, in contrast to the other pulsed voltammetric techniques, square-wave voltammetry causes very little of the depletion that gives rise to distortion of the current – voltage waveform. Accordingly, square-wave voltammetry is uniquely

capable of benefiting from high scan rates. A typical compromise frequency for the waveform is 200 Hz. Coupled with a dE value of 10 mV, this gives rise to a scan rate of 2 V/s. The scan rate is limited by a concomitant increase in the capacitive current. At a solid electrode, the square-wave method is no better than pulsed-voltammetric techniques with respect to rejection of the capacitive current.

Another significant advantage of square-wave technology is the possibility of rejecting a wide range of background currents. With respect to capacitive currents this is achieved by the subtraction of two currents in a manner analogous to differential-pulse voltammetry. Slowly varying capacitive currents that arise when surface groups reorganize on certain types of solid electrodes are also eliminated provided the rate of variance is sufficiently low.

Figure 18. Decrease in faradaic and capacitive current with elapsed time from the imposition of a potential pulse $i^{\bullet}$ = Faradaic current; $i^{\sim}$ = Capacitive current

Amperometry. Amperometry has traditionally been concerned with maintaining a fixed potential between two electrodes, but pulsed techniques have attracted considerable attention as well. The applied potential at which current measurements are made is usually selected to correspond to the mass-transport-limited portion of the corresponding voltammetric scan. Table 9 summarizes the various amperometric methods.

Theoretically, the current obtained in a quiescent solution at a conventional set of electrodes gradually decays to zero according to the Cottrell equation [71]:

$$i_j = nFAC\,(D/\pi t)^{1/2} \tag{7}$$

where t is the elapsed time from application of the potential pulse.

The observed decrease in current is due to a slow spread of the diffusion layer out into the bulk solution, with a concomitant decrease in the concentration gradient. In practice, this process continues for ca. 100 s, after which random convection processes in the solution take over, putting an end to further movement of the diffusion layer. Waiting nearly two minutes to obtain a steady-state current is not a particularly attractive alternative. Accordingly, in amperometric measurements for sensor applications the spread of the diffusion layer is controlled by invoking one or more of the following mechanisms:

1) *Convective Diffusion.* From a practical point of view, convective diffusion can be achieved in two ways: by moving the solution relative to the electrode, or moving the electrode relative to the solution. Of the systems developed to move the electrode, only one merits consideration here, the *rotating disc electrode* (RDE), but there are few possibilities for realizing this electrode in a sensor.
2) *Imposition of a Physical Barrier in the Form of a Membrane.* There are four primary advantages to covering the electrodes of an amperometric device with a membrane permeable only to the analyte: (a) poisoning of the electrodes by electroactive or surface active species is limited; (b) the resolution of the system is enhanced, because extraneous electroactive species that might otherwise undergo electron transfer at the electrode are excluded; (c) the composition of the electrolyte occupying the space between the membrane and the electrodes remains constant; and (d) the membrane forms a physical barrier to prevent the diffusion layer from spreading into the bulk solution.
The limiting current obtained at a membrane-covered amperometric device is a function of time, reaching in due course a steady-state value. The current – time transient cannot be described by a single equation, because different transport mechanisms operate during this time interval. For a typical membrane-covered amperometric oxygen detector with an electrolyte thickness of

Table 9. Amperometric methods (adapted from [26])

Method	Applied potential	Measured signal	Comments
Chronoamperometry			the electrode potential is pulsed to a region in which the analyte is electroactive; a decaying current reflects the growth of the diffusion layer
Pulsed amperometry			the electrode potential is pulsed briefly to a region in which the analyte is electroactive; between pulses the diffusion layer may be eliminated by forced or natural convection
Pulsed amperometric detection			electrode conditioning, analyte sorption, and catalytic electrooxidation are all promoted by the use of this waveform; the current is measured only during the last part of the cycle (region *A*)

10 µm, a membrane thickness of 20 µm, an electrode radius > 2 mm, and a diffusion coefficient for the analyte two orders of magnitude lower in the membrane than in the electrolyte solution, it can be shown that the current – time transient can be described by three equations. For times > 20 s after the imposition of the potential pulse to the electroactive region, the limiting current is given by

$$i_j = nFAC\,(P_m/d) \tag{8}$$

where P_m is the permeability coefficient of the membrane and d is its thickness.

An important consequence of this equation is that the limiting current is a function of the permeability of the membrane. Unfortunately, membrane properties such as permeability are themselves a function of time and ambient conditions, particularly temperature. Accordingly, there are advantages to operating membrane- covered detectors away from this steady-state condition. For a typical detector, the limiting current < 100 ms after imposition of the measurement potential pulse is given by

$$i_j = nFAC\,(K_b/K_0)\,(D_e/\pi t)^{1/2} \tag{9}$$

where t is elapsed time since imposition of the measuring potential, D_e is the diffusion coefficient for the analyte in the electrolyte, and K_b is the distribution coefficient for the analyte at the internal electrolyte – membrane interface. The ratio K_b/K_0 expresses the salting-out effect of the electrolyte solution.

In effect this equation describes the diffusion-limited current arising within the electrolyte layer. In other words, the diffusion layer has not had sufficient time to spread to the membrane, and so the limiting current is completely independent of the membrane. This has the advantage that alterations in membrane characteristics, as well as alterations in ambient conditions that might affect membrane performance, have no effect whatsoever on the limiting current. One of the factors to which this applies is stirring. Under steady-state conditions, stirring of some type is necessary to prevent changes that would otherwise be caused by the diffusion layer moving out into the bulk solution,

although the rate of such stirring is not critical. When transient measurements are made, no stirring whatsoever is required. The true situation regarding transient measurements with amperometric devices is actually not quite so simple as depicted here; for example, there is also a need to take into account contributions from the capacitive current.

The classic amperometric membrane-covered device is the Clark oxygen sensor [72], which consists of a platinum working electrode, an Ag/AgCl reference electrode, a KCl electrolyte solution, and an oxygen-permeable membrane made of teflon or silicone rubber. Figure 19 is a schematic diagram of such a sensor. Dissolved oxygen passes through the permeable membrane, after which it is reduced at the working electrode. The current flow is proportional to the amount of oxygen present in the solution. The following reactions take place at the surface of the working electrode:

$$O_2 + 2\,H_2O + 2\,e \longrightarrow [H_2O_2] + 2\,OH^-$$

$$[H_2O_2] + 2\,e \longrightarrow 2\,OH^-$$

A separate polarographic wave corresponding to the reduction of hydrogen peroxide is observed only with a mercury cathode, which produces two waves for the reduction of oxygen. At other electrodes (Pt, Au, C) only one fourelectron wave is obtained, corresponding to complete reduction to four hydroxide ions [73]. The potential E of the working electrode (at the diffusion-limiting current plateau) usually lies between -0.6 and -0.9 V vs. Ag/AgCl.

Progress in semiconductor technology during recent years has made it possible to miniaturize the classical oxygen sensor [74–77] for use as a transducer in several chemical and biochemical sensors.

3) *Pulsing the Electrode from a Region of Electroinactivity to a Region of Transport-Controlled Electroactivity, after which the Potential is Restored to the Electroinactive Region.* For electrochemical sensors without membranes, applying a potential pulse from a region of electroinactivity to a region of electroactivity has several advantages. For example, the duty cycle of the pulse can be arranged in such a way that the electrode spends the majority of its time at the electroinactive potential. Under these circumstances electrode reactions give rise to products that poison the electrode, but these products are of minimal significance because they are produced at a very low rate. Moreover, natural processes of convection are able to redistribute the electroactive species during the time that the electrode is at the rest potential, thus limiting the spread of the diffusion layer into the bulk solution. The drawback to this technique is the appearance of a capacitive current. Limiting the size of the pulse decreases the contribution of this current, but a small pulse from a rest potential to the electroactive potential is achievable only for reversible electrode reactions. The alternative is to allow sufficient time for the capacitive current to decay away between imposition of the potential pulse and measurement of the current.

4) *Pulsed Amperometric Detection* [78]. This is a relatively new technique that has made possible the direct amperometric determination of many compounds formerly considered unsuitable for analysis in this way. The corresponding waveform is illustrated in Table 9. This rather complex waveform serves several purposes. On platinum, for example, and at the extreme anodic potential, surface-confined oxidation products that tend to poison the electrode are desorbed. This process occurs concurrently with the formation of PtO_2 on the surface. At the cathodic potential the surface oxide is subsequently reduced, and a clean platinum surface is regenerated. In some cases, sorption of the analyte occurs at this cathodic potential, so the analytical signal is recorded at an intermediate potential. Several different mechanisms can give rise to this signal. Electroactive species that are not adsorbed at the electrode may undergo conventional oxidative electrode reactions. Alternatively, electroactive species that are adsorbed at the electrode during the cathodic swing of the cleaning cycle may undergo either conventional oxidative desorption or oxidative desorption catalyzed by an oxide species on the surface of the electrode. For many compounds the latter reaction is much more favorable from a thermodynamic

point of view than oxidation in the absence of a catalyst. This type of reaction occurs most readily when both the analyte and the oxide are confined to the surface. Finally, adsorbed electroinactive analytes may also be detected by virtue of their ability to block the electrode sites at which the PtOH formation occurs. Consequently, any faradaic current arising from the oxidation of platinum is diminished in the presence of adsorbed electroinactive analyte.

5) *Microelectrodes.* Electroanalytical applications using microelectrodes have become more common in recent years [79–83] as silicon technology has opened new possibilities for constructing electrodes with micrometer and submicrometer dimensions [84], [85]. The rate of electrolysis at such electrodes is approximately equivalent to the rate of diffusion. Linear-sweep voltammetry in this case gives rise to the same S-shaped current – voltage curves observed with rotating disc or dropping mercury electrodes. The time-dependent current arising at a microelectrode is given by the equation for the chronoamperometric current at a conventional electrode under spherical diffusion conditions:

$$i_t = nFACD\left[\left\{1/(tD\pi)^{1/2}\right\} + \{1/r\}\right] \quad (10)$$

where r is the electrode radius. Indeed, a sphere or hemisphere represents a good model for the diffusion zone that surrounds such an electrode, and because of enhanced mass transport to the electrode, a steady-state current is achieved very rapidly once a potential pulse has been applied to the electrode. Although the diffusion zone is large in this case relative to the electrode surface, it is small compared to the zone surrounding a conventional electrode. This small size means that the faradaic current associated with a microelectrode is relatively immune to the effects of convection in the bulk solution, and the current in a flowing stream is independent of the rate of flow. Decreased effects due to capacitance and resistance at microelectrodes, coupled with high mass-transport rates, make it possible for electrochemical measurements to be obtained in this way in cells containing highly resistive solutions. In fact, provided sufficient free carrier is available to charge the double layer, microelectrodes can be used for direct electrochemical measurements in the gas phase [86]. One drawback of employing working electrodes with diameters less than about 5 μm are the small currents which will flow through such small interfaces. Current measurements in the pA range are prone to electromagnetic interferences (e.g., AC pick-up) and thus, the electric noise level can be a limiting factor. This problem can be solved by employing an array of microelectrodes all at the same potential and separated from each other by about ten times their diameter. Such arrays have been constructed and have shown all the benefits of single microelectrodes [87], [88].

2.3.1.3. Conductance Devices

Conductance is used as a sensor signal in two different areas of sensor technology. On one hand it

is possible to determine the electrolytic conductance of electrolytes, which permits conclusions to be reached on a wide range of electrolyte properties. Moreover, partial pressures of gaseous compounds can be determined in the gas phase by examining their influence on the electronic conductance of such materials as semiconducting oxides [89–92].

Conductometric Sensors for Monitoring Electrolytic Conductance. *Introduction.* Electrolytic conductance serves as a useful signal of the electrical conductivity of mainly aqueous electrolyte solutions, and *conductometry* has been developed into an electrochemical analytical method based on measuring the conductance in electrolyte solutions. All ions in such a solution act as current carriers as a function of their mobility, charge, and concentration. For this reason conductivity measurements are inherently nonselective with respect to any system to which a changing voltage difference has been applied and the diffusion current is measured. Despite this disadvantage, conductivity measurements are indispensable sources of information, especially for monitoring the chemical purity of water samples. In pollution control, conductometric data provide a reliable measure of the total content of ionic pollutants, which is sometimes all that is required. Advantages of conductivity detectors include their universal applicability, simplicity, low price, and wide effective concentration range. Conductivity measurement is one of the most commonly used electrochemical techniques in the control of industrial chemical processes. Conductivity detectors are also employed in ion chromatography and HPLC as a way of detecting separated ions in the eluate from a column [93]. Furthermore, conductometric analyzers are used in the monitoring of atmospheric pollutants such as acidic or alkaline gases (e.g., HCl, CO_2, SO_2, SO_3, NH_3) after these have been transferred as ions into aqueous solution [94], [95]. Conductivity measurements are nondestructive with respect to the sample, and they are always advantageous when electrolytes must be determined in a medium of low self- conductivity.

Definitions. The electrolytic conductivity σ of a solution is defined as the conductance G of the electrolyte between two electrodes, each with an area A, separated by a distance d. The conductivity σ is then given by

$$\sigma = G \cdot d/A \tag{11}$$

The traditional unit of electrolytic conductivity, Siemens per centimeter (S/cm), has been replaced by S/m [96], but the new unit has not yet been accepted widely by the instrument-producing industry, nor by the users of conductivity measurement devices. The English-language literature has historically made use of the "mho" (reciprocal ohm), which is another way of expressing the conductance G. The quotient d/A (cm^{-1}) is defined as the cell constant k, and depends on the geometry of the cell. The electric field is never homogeneous over the cross section of a real cell, so it is not in fact possible to calculate a cell constant k directly from geometric dimensions; it must instead be determined with calibration solutions of known conductivity [97].

The temperature dependence of σ can be deduced from ionic mobilities. This dependence is expressed in terms of the temperature coefficient $\alpha = (d\sigma/dT)(1/\sigma)$, which generally has a positive value between 1 and 3 % per degree Celsius. Knowledge of α in turn makes it possible to calculate conductivities at temperatures other than the temperature of measurement. Whenever the need arises to determine the conductivity of a solution with a very low electrolyte concentration it is essential also to take into account the self-dissociation of pure water, which has a conductivity $\sigma_{25} = 0.05483$ µS/cm.

Measurement Principles. The equipment used for measuring conductance usually consists of a conductivity sensor, a measuring attachment, and a temperature- compensation unit. Conductance values are obtained by establishing either the current flow between a set of electrodes subjected to a constant AC voltage, or the current induced in the secondary coil of a transformer connected to the primary coil by the electrolyte of interest. Capacitive coupled cells have been developed as well, but because of their expensive construction they are no longer of interest [98–101].

Two-Electrode Cells. Two-electrode cells are equipped with a pair of electrodes across which both the voltage and the current can be measured. Use of an AC voltage source is a convenient way of avoiding polarization effects at the

electrode/electrolyte interface and electrolyte decomposition. Figure 20 illustrates a typical construction together with the corresponding equivalent circuit. The advantage of this design is the simplicity of both the cell and the measuring attachment.

Figure 20. Depiction of a two-electrode cell (A) together with the corresponding equivalent circuit (B)
The dashed rectangle includes all network components involving the electrolyte in contact with the electrodes.
a) Cell body; b) Leads; c) Electrode; d) Sample
R_E = Electrolyte resistance; R_1, $R_{1'}$ = Charge-transfer resistances at the interface electrode – electrolyte; C_1, $C_{1'}$ = Capacitance of the electrochemical double layer; R_2, C_2 = Shunt circuit in the cell

Disadvantages are associated with the need for measuring both the current and the voltage at a single electrode, which may lead to electrode polarization and a measured conductivity lower than the true value. The resistance contributed by a cell in contact with a sample must also be taken into consideration in conjunction with other resistance and capacitance values. At high conductivities ($\sigma > 1$ mS/cm) the resistance of the connecting wires is another significant factor, and electrode reactions can cause polarization of the electrode – electrolyte interface. These problems can be overcome most effectively with an AC voltage oscillating at 1 – 5 kHz and electrode materials with minimum polarizability due to a large surface area, such as platinum covered with a layer of platinum black. At low conductivities ($\sigma < 10$ µS/cm) measured conductivity values may be too high because of capacitive – ohmic shunts caused by the cell body or the connecting wires ("Parker effect"). Contamination by adsorbed ions is also a problem with porous electrodes. The measurement frequency should therefore be kept as low as possible, and the electrodes should be smooth. Resistive precipitates at the electrode surface are sometimes a cause of artificially low conductivity.

For the reasons mentioned above, the "cell constant" is in fact constant only over a limited conductivity range. Suitable values for the cell constant depend on the anticipated level of conductivity:

Expected conductivity	Cell constant
< 0.1 µS/cm – 1 mS/cm	0.1 cm^{-1}
1 µS/cm – 100 mS/cm	1.0 cm^{-1}
10 µS/cm – 1 S/cm	10 cm^{-1}

Four-Electrode Cells. The four-electrode cell was developed as a way of overcoming the problems inherent in two-electrode cells. Two current electrodes in this case generate an electric field, and two separate voltage electrodes are provided for measuring the voltage drop with the aid of a high-impedance amplifier. This design is insensitive to polarization effects, and it also avoids interference from insulating films or precipitates because these are formed outside the zone of measurement. The result is a single system that can be used to measure any conductivity > 1 µS/cm.

Inductively Coupled Cells. The principle underlying inductively coupled conductivity cells is very simple. Two coils of a transformer are shielded from each other magnetically such that the only coupling loop is formed by an insulating tube filled with the sample. An AC voltage in the primary coil induces an AC current in the sample, the magnitude of which depends on the dimensions of the loop and the conductivity of the sample. The voltage induced in the second coil

depends only on the input voltage of the primary coil and the conductance of the sample. Typical working frequencies are 80 – 200 Hz. An advantage of these cells is that they permit contactless measurement. Very high conductivities (>1 S/cm) can be measured without polarization errors because of the contactless decoupling of the signal. Even thin resistive films within the tube fail to falsify the measured conductivity. Another advantage associated with cells of this type is the possibility of encapsulating the entire device in a polymer offering high chemical resistance. Inductively coupled conductivity cells are thus of special interest for measurements in highly conducting and aggressive media [102].

Ion-Selective Conductometric Microsensors. The greatest problem in miniaturizing potentiometry was the lack of a longer working reference electrode. The development of ion-selective conductometric microsensors mainly for cations such as H^+, Li^+, Na^+, K^+, NH^{4+}, Ca^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}, and Ag^+ thus far in the ICB Muenster overcomes this problem [103]. In principle, they are partly based on the ion-selective optodes introduced by the late Prof. Simon who showed that the measured ion can also be selectively extracted into an ionophore-based membrane. In order to maintain electroneutrality in the bulk of the membrane a co-immobilized indicator dye looses a proton which passes into the sample solution and thereby changes the color. The influx of the measured cation, which will be complexed by the neutral ionophore and leads to an even larger cation complex in the PVC membrane, is electrically compensated by an outflux of protons that dissociate from a neutral lipohilic acid. This exchange of protons from the membrane against the measured cation will cause the membrane conductivity to change. This can easily be followed by a planar interdigital electrode array onto which a corresponding membrane is drop-coated. In order to keep the lipophilic acid in the membrane in its neutral state and in order to control the interfacial ion-exchange processes in a reproducible way, all measurements must be performed in a buffer of an appropriately chosen and constant pH. Figure 21 shows the measuring set-up and Figure 22 some results of a valinomycin based potassium-selective membrane. The length A of the interdigital electrode fingers is only about 1 mm and α the width of a finger and spacing lies in the region of about 10 µm. The membrane thickness is δ in the range 0.5 – 5 µm. The membrane cocktail – similar to the one in case of ISE membranes – can be brought onto the interdigital electrode array by dip- or drop-coating. U_{in} an alternating voltage in the range 10 – 100 mV and is applied via the corresponding output of a lock-in amplifier. U_{out} at the load resistor is fed to the input of the lock-in amplifier. The in-phase component of the complex impedance is measured and evaluated. In general, the characteristics of those bulk conductive microsensors resemble those of the corresponding ISE membranes with slight variations in the selectivity pattern. The advantage is that the accuracy of their measurements does not drop with increasing charge of the measured cation. With a membrane thickness in the region of 1 µm the response time is in the second range. A difference compared with ISE membranes lies in the increased concentration of ionophore that is added up to about 5 % by weight. These ion-selective conductometric microsensors do not need any reference electrode and can be scaled down to the µm range. The lifetime depends on the lipophilicity of the ionophore and plasticizer. Normally they work for up to several weeks and show a relatively small drift. The further advantages are that they are easily produced by CMOS technology and open also the way to the detection of higher charged analyte ions for which the Nernst equation only allows a small mV change per decade concentration change. Despite the fact that their selectivity pattern is more similar to the one of the corresponding optodes they lack the drawback of the latter with respect of chromo- or fluorophore bleaching. Furthermore, in case of light absorption measurements a compromise between sensitivity (depending on the thickness) and response time must be made.

Because of the excellent sensitivity, ease of fabrication, and storage capabilities these microsensors are ideally suited for medical bedside monitoring or "point of care" devices. Figure 23 shows a novel cartridge developed at the ICB Muenster for blood electrolyte measurements. In comparison with existing devices no open blood transfer with a certain risk of infection is needed. In another special version of the cartridge, a valve allows the continuous uptake of blood in the syringe needing only the first 100 µL for the electrolyte. The content of the syringe can

then be analyzed as usual. The evaluation is performed by putting the cartridge in a hand-held readout unit. Note, prior to blood sampling the same cartridge has to be checked by the same readout unit for quality control reasons and recalibration.

Conductometric Sensors for Monitoring Gaseous Compounds. *Introduction.* Gaseous compounds in the gas phase are detected with chemically sensitive devices that respond electrically to changes in conductance. BRATTAIN and BARDEEN (using germanium, in 1952) [104] and HEILAND (zinc oxide, 1954) [105] were the first to observe modulation of the electrical conductance of a solid-state device by gases from the surrounding atmosphere. The most commonly used material for conductometric solid-state gas sensors is now tin dioxide [106]. As noted previously (Section 2.2.2) commercial sensors based on polycrystalline SnO_2 ("Taguchi sensors") [107] are produced by companies such as Figaro Inc., for a wide range of industrial and domestic applications, including gas monitors, leak detectors, and alarm systems for toxic or inflammable gases. Apart from SnO_2, an *n*-semiconductor, many other inorganic semiconducting oxides can serve as sensitive materials in gas sensors, including TiO_2, ZnO, and Fe_2O_3 with various additives and dopants [13], [108]. Certain organic semiconductors such as phthalocyanines with appropriate central metal atoms, or polymers like polypyrrole or polysiloxane, also show sensitivity to gaseous compounds. These sensors are often referred to as homogeneous or heterogeneous semiconductors, or as dielectric sensors. Detailed lists of materials sensitive to detectable gaseous compounds together with the corresponding operating temperatures are provided in [89–92], [108]. The design principle upon which such sensors are based is quite simple: a sensitive semiconducting sample is placed between two metallic contacts, and the combination is equipped with a resistance heater capable of maintaining the appropriate working temperature, usually between 100 °C and 700 °C. Semiconductor sensors have dimensions in the range of millimeters, and are easily fabricated by either thick- or thin-film technology [109].

Heterogeneous Semiconductor Sensors. The response of a heterogeneous semiconductor sensor is based on changes in surface conductance as mentioned in the introduction, mainly due to changes in the free electron concentration within a thin surface layer of the semiconductor as a consequence of charge exchange with adsorbed species accompanying chemisorption or heterogeneous reactions [33] (see Section 2.2.2). The most commonly used semiconducting materials are the two very stable oxides SnO_2 [110], [111] and ZnO [112]. Because the conductance change is a surface phenomenon, the ratio of surface to bulk material should be made as large as possible (using thin layers) to maximize the effect. For sintered polycrystalline materials the grain size should also be as small as possible.

At a given temperature the number of gas molecules adsorbed at a semiconductor surface – hence the conductance – correlates exponentially with the partial pressure of the gas. Oxidizing gaseous compounds such as oxygen, nitrogen dioxide, and chlorine cause a resistance increase by extracting electrons from the conduction band of an *n*-type semiconductor, while reducing gases like hydrogen, carbon monoxide, methane, hydrocarbons, or alcohols lead to a resistance decrease since they are themselves oxidized by the adsorbed oxygen . Humidity decreases the resistance of an *n*-type semiconductor, causing considerable interference.

Response times for sensors of this type are usually in the range of seconds or minutes. For some gases it has been found that catalytic effects at the semiconductor surface can have a

significant impact on the response. Thus, sensor properties such as response and selectivity can be improved by adding catalytically active metals like palladium, rhodium, silver, or platinum. This doping of the semiconductor surface is one important way of modifying the selectivity of a sensor [113–115], but another possibility for adjusting sensor properties for a particular application is careful selection of the working temperature [116].

Figure 22. Simplified electronic equivalent circuit (measured is R_B = bulk membrane resistance) and impedance spectra of the real part (admittance) in a 1 M $Ca(NO_3)_2$ (!) supporting electrolyte and increasing K^+ concentrations with a valinomycin-based potassium conductometric microsensor. Note that even μM amounts of K^+ ions in a well conducting electrolyte solution can be sensed

The influence of temperature on the selectivity of a sensor depends on the fact that each gas has its own *characteristic temperature:* a temperature at which the reversible relationship between gas concentration and the concentration of electrons at the semiconductor surface (and therefore the conductance) reaches a maximum [110]. Working temperatures for SnO_2-based sensors usually lie between 200 °C and 450 °C depending on the application.

Various techniques are used for the fabrication of semiconductor sensors. Conductance sensors from structurized sintered polycrystalline ceramics can be produced by thick- or thin-film technology. Chemically sensitive materials in the form of single crystals or whiskers can be attached to electrodes by thin- or thick-film techniques as well. Mass production of sensors requires that the resulting devices be characterized by a defined level of conductance. For example, the conductance of polycrystalline SnO_2 can be adjusted by subsequent thermal treatment > 800 °C under a controlled partial pressure of oxygen. Another approach to defined conductance involves doping the semiconductor with antimony or fluorine. The reproducibility and stability of a sensor signal is generally diminished by irreversible changes in the defect structure of the semiconductor surface.

Figure 23. Measuring principle of a cartridge system using microsensors for the case of medical "point of care" blood electrolyte measurements
A) Storage of the cartridge with a standard solution; recall of data; measuring of the standard solution for plausibility and quality controls.
B) Drawing of the blood sample; displacement of standard; disconnection of the cartridge; insertion of the cartridge into the analyzer; measuring of the undiluted blood sample.

Homogeneous Semiconductor Sensors. The effectiveness of this type of semiconductor sensor depends on changes in bulk conductance. The stoichiometry and concentration of bulk point defects, and thus the conductance of such materials, is a function of the partial pressure of a gaseous analyte. Conductance changes arise through reversible changes in small deviations from ideal stoichiometry, which in turn influence the concentrations of bulk point defects and free electrons [33]. The deviation from ideal stoichiometric composition is usually very small; for example, in $Cu_{2-x}O$ the deficit x in the Cu

ratio is on the order of 0.001. Since conductance and deviation from ideal stoichiometry are proportional, a measured conductance can be used to determine a corresponding partial pressure. Regarding the kinetics of these sensors, an important factor is diffusion of a compound like oxygen or the corresponding lattice defects that compensate for nonideal stoichiometry within the bulk of the semiconductor. Any gaseous reaction involving point defects at the surface of the semiconductor must also be appropriately fast. Both requirements can be met through the combination of high temperature and a catalytic coating (e.g., Pt).

Most bulk-conductance sensors consist of semiconducting oxides the conductance of which changes with the partial pressure of oxygen. They are used primarily for monitoring oxygen partial pressures in the air or in combustion gases. Titanium dioxide (TiO_2) is one of the most commonly used homogeneous sensor materials for the determination of oxygen partial pressures [117]. At 900 °C and an oxygen partial pressure of 0.1 MPa, TiO_2 has precisely the stoichiometric composition. At lower oxygen partial pressures TiO_2 has an oxygen deficit x expressed by the formula TiO_{2-x}. This oxygen deficit specifies the number of unoccupied oxygen sites and the corresponding excess of trivalent titanium in the lattice. Both defects act as electron donors, thereby contributing to the concentration of free electrons in the conductance band of the semiconductor. The oxygen deficit, and thus the conductance, varies inversely with the partial pressure of oxygen in a characteristic way. Thus, the conductance σ_e of an n-type semiconducting oxide like TiO_{2-x}, CeO_{2-x}, or Nb_2O_{5-x} is given by the equation:

$$\sigma_e = \text{const}\,(T)\cdot p\,(O_2)^{-1/m} \tag{12}$$

where const(T) is a temperature-dependent constant and m usually varies between 4 and 8 depending on the nature of the disorder in the oxide structure.

On the other hand, p-type semiconducting oxides like $Cu_{2-x}O$, $Ni_{1-x}O$, and $Co_{1-x}O$ have a deficit x of metal relative to ideal stoichiometry. This deficit increases with increasing oxygen partial pressure. Ionic lattice defects occurring in oxides of this type act as electron acceptors. In this case the concentration of the defects, and therefore the conductance, increases with increasing oxygen partial pressure according to the expression:

$$\sigma_e = \text{const}\,(T)\cdot p\,(O_2)^{1/m} \tag{13}$$

Here again, m usually varies between 4 and 8.

The strong exponential dependence of const(T) on temperature is a great disadvantage with homogeneous semiconductor sensors, one that can lead to large measurement errors. Nevertheless, appropriate sensor design makes it possible to compensate for the temperature dependence. In the case of a TiO_2 combustion-gas sensor, for example, the conductance of an oxygen-sensitive TiO_2 sample can be compared with that of a second sample displaying the same response to temperature but coated in such a way as to eliminate its sensitivity to gas composition. The conductance difference between the two samples is then a function only of the gas composition, not of fluctuations in the temperature.

An important requirement for any metal oxide under consideration for use as a homogeneous semiconducting sensor is that it display a sufficiently high bulk diffusion coefficient $\tilde{D}$ for the conductance-determining species. Response times t for oxide layers with a thickness y can be estimated from the Einstein equation:

$$y^2 = 2\tilde{D}\cdot t \tag{14}$$

For example, a Cu_2O layer with a thickness of 1 µm reaches a response time of ca. 1 ms, corresponding to a diffusion coefficient of ca. $10^{-5}\,cm^2\,s^{-1}$, only upon heating to 700–800 °C. The diffusion coefficient can be altered by doping, but it also depends on the extent of deviation from ideal stoichiometry.

A number of oxides (e.g., TiO_2, CeO_2, Nb_2O_5, CoO) or titanates with a perovskite structure (Ba/Sr/$CaTiO_3$) have been successfully tested for application as extremely fast responding oxygen sensors [118–120] allowing individual cylinder control in automobile engines. Most of these investigations involved determination of the oxygen partial pressure in exhaust gases from combustion processes at partial pressures between 10 and 10^{-18} kPa. At low oxygen partial pressures and high temperature, certain oxides (e.g., Cu_2O, CoO, NiO) are unsuitable because of their reduction to pure metal.

Sensors based on TiO_2 ceramics are by far the most highly developed devices. These consist of porous sintered ceramic materials with a platinum surface doping, and are used to determine air – fuel ratios in the exhaust gases of combustion engines.

Apart from TiO_2, a number of other semiconducting oxides might be useful as sensor materials for special applications over limited ranges of oxygen partial pressure, as in monitoring the level of oxygen in inert gases. There is also a good possibility of optimizing various ternary and higher oxide combinations for sensor application by suitable choice of composition with respect to stability, diffusion, and surface properties [121–123]. Thus, barium and strontium ferrates show conductances with considerably less temperature dependence relative to TiO_2 or CoO.

Organic Conductometric Sensors. For several years, certain organic semiconducting polymers have attracted attention in the search for new chemical sensors [124]. The possibility of utilizing conductivity changes induced by gases adsorbed on organic materials is interesting for a number of reasons. For example, it might permit the detection of very low levels of atmospheric pollutants. Moreover, organic materials are much more easily modified than inorganic materials with respect to such characteristics as sensitivity, working temperature, and selectivity. The greatest disadvantage of organic materials in gas detection is that they are usually very poor conductors, and conductivity measurements would be correspondingly difficult. Also, organic materials are thermally unstable, so it is often impossible to use them at temperatures at which gas – solid interactions proceed rapidly and reversibly.

Phthalocyanines constitute one group of organic materials with thermal stability $> 400\,^{\circ}C$, and they are usually considered to have semiconducting rather than insulating properties. Thin layers of phthalocyanine complexes based on metals like lead [125] and copper [126] have been particularly carefully studied as potential gas sensors [127]. The conductance of these films is a very sensitive function of gases with electron-acceptor properties, including nitrogen dioxide, chlorine, and iodine. Films of phthalocyanines with various central metal atoms can be deposited on substrates with a planar interdigital electrode array by sublimation or screen printing. Changing the nature of the central metal atom makes it possible to adjust the sensitivity and selectivity of a phthalocyanine film in accordance with the proposed application [128–133].

Another organic semiconductor with gas-sensitive properties is polypyrrole. Chemiresistors with ambient-temperature gas sensitivity to both electron-donating and electron-accepting gases have been achieved using thin polypyrrole films prepared by electrochemical polymerization on electrodes. Sensitivities have been investigated toward such gases as nitrogen dioxide [134], ammonia [135], and methanol [136], [137]. A wide variety of polymers of this type is available, including substituted polypyrroles, polythiophenes, polyindoles, and polyanilines. This is leading the way to combining more of these sensors in sensor arrays and using chemometrics to evaluate unknown smells (electronic noses).

Humidity Sensors. Humidity sensors are devices that respond to changes in water-vapor pressure by a change in electrical resistance, capacitance, or a combination of the two as reflected in the impedance. The sensitive material might be an electrolyte, an organic polymer, or a metal oxide subject to a change in ionic – electronic conductivity or capacitance with respect to humidity as a consequence of physical adsorption or absorption of water molecules. In general these devices offer a very cost-effective continuous or spot- check approach to monitoring humidity in air and other gases [138], [139].

Electrolyte humidity sensors. Electrolyte humidity sensors are based on an electrolyte solution (e.g., the hygroscopic LiCl) the ion conductivity of which changes as a result of evaporation or condensation of water in response to changes in the relative humidity of the surrounding atmosphere. The fabrication of these sensors is quite straightforward. A porous substrate or an organic binder is impregnated with the electrolyte in such a way as to prevent electrolyte from flowing out of the sensor even at very high humidity. Contact is maintained with platinum electrodes on both sides of the substrate. Even thin films of potassium metaphosphate or barium fluorite are suitable for humidity measurements. Despite their slow response and limited linear

range these sensors have an outstanding reputation due to good reproducibility, long-term stability, and low cost.

Ceramic Humidity Sensors. The first widely-used ceramic humidity sensor was the aluminum oxide sensor, in which aluminum is oxidized anodically in an acidic solution to form a porous oxide film, sometimes less than 1 μm thick, that displays the necessary hygroscopicity. Adsorption of water molecules causes a decrease in resistance and an increase in capacitance, which is reversed by subsequent desorption. Other materials are also used in humidity sensors, including ZnO with added Li_2O and V_2O_5, colloidal Fe_3O_4, α-Fe_2O_3, mixed oxides of TiO_2 and SnO_2, $MgCr_2O_4-TiO_2$, $TiO_2-V_2O_5$, $ZnCr_2O_4-LiZnVO_4$, $MgAl_2O_3$, $MgFe_2O_4$, or $H_3PO_4-ZrSiO_2$, as well as $PbCrO_4$ with added alkali oxide [140]. Sometimes the signal of such a sensor is subject to drift as a result of changes in the surface structure or contamination from other adsorbed gases. Nevertheless, reproducibility can be restored by heat cleaning.

The most important considerations with respect to sensor characteristics are surface properties (hydrophilic – hydrophobic), pore-size distribution, and electrical resistance. To ensure adequate sensitivity and response a sensor of this type should consist of a very thin film of porous ceramic with a porosity $> 30\,\%$. The contacting electrodes may be interdigitated or porous sandwich-type structures made from noble metals (e.g., Pd, Pt, Au) and so constructed that they do not obstruct the pores of the oxide film. Humidity affects not only the resistance of a porous ceramic but also its capacitance by extending the surface area in contact with the electrodes. The high dielectric constant of adsorbed water molecules also plays an important role.

Polymeric Humidity Sensors. Certain polymers are capable of taking up water as a function of the relative humidity of the surrounding atmosphere, leading to changes in such mechanical and electrical properties as volume, resistance, and dielectric characteristics. A number of polymers have been used as sensitive materials in this regard, including ion-exchange resins, polymer electrolytes, hydrophilic polymers, and hygroscopic resins [141]. Hydrophilic polymers [e.g., poly(ethylene oxide) – sorbitol] swell by absorption of water. If such a polymer is filled (mixed) with carbon or metal powder of very small particle size, the resistance observed depends on the distance and the number of particles that are in contact with each other. Uptake of water leads to swelling of the polymer and disturbance of the ohmic contacts between conducting particles, which in turn increases the resistance. For this reason the resistance correlates with humidity. Useful materials include cellulose esters and polyalcohols.

The resistance of polymers with dissociable groups (e.g., sulfonates, amines, amides, or even hydroxides) also depends on humidity. The resistance of such polymers in fact decreases with absorption of water because of ionic dissociation and an increase in ionic conduction.

The absorption of water by polymers is especially suited to the development of a capacitive humidity sensor based on the high dielectric constant of water, since capacitance depends on the area, the thickness, and the dielectric constant of a dielectric. Uptake of water causes an increase in the dielectric constant followed by an increase in capacitance. Polyimide is a suitable sensitive material, but so are certain inorganic ceramics such as Al_2O_3 [142] and low-density Ta_2O_5, which change their capacitance with the formation of water dipoles. Low-density Ta_2O_5 layers can be formed by anodic oxidation of sputtered tantalum films, whereas polyimide films are deposited by spin coating and subsequent polymerization.

Conducting Polymer-Based Gas Sensors. The above mentioned ion-selective conductometric microsensors can easily be transformed into gas sensors by omitting the ionophore and adding an organic salt for a certain ground conductivity instead. These PVC/plasticizer membranes are sensitive to reaction with certain gases that can enter the membrane phase and alter the conductivity of the organic ions either by increasing their dissociation from an ion-pair situation or by increasing their diffusional property due to membrane swelling. Figure 24 gives an example of when the salt and the plasticizer are present simultaneously. The selectivity for a certain gas can be modulated by changing the type and concentration of the latter. Therefore, much more variations are possible compared with other polymer-based gas sensors based only on their known gas chromatographic distribu-

tion behavior. A typical membrane composition is: about 50 % PVC, 30 – 35 % plasticizer, the remainder being the organic salt such as tetraalkylammonium halides. The compounds are as usual dissolved in tetrahydrofurane and then drop-coated on the interdigital electrode array with similar dimensions as in the above mentioned case of the conductometric ion-selective microsensors.

Figure 24. Variations of the sensor membrane composition. Sensor response against different concentrations of ethanol (500 ppm, 1000 ppm, 2000 ppm).
Polymer: polyisobutylene; plasticizer: ortho-nitrophenyloctylether; organic salt: tetraoctylammoniumbromide

Gases that can be detected in the lower ppm range with response time of a few seconds are so far: tetrachloroethene, ethanol, benzene, toluol, and xylene. The measurement technique is exactly the same as with the conductometric ion sensors for application in liquids (Fig. 21). Compared with other gas-sensing devices the measurements are performed at room temperature. Thus, the energy consumption is very low, which will open the way to hand-held instruments. Unfortunately the optimization of the membrane composition for one gaseous analyte has yet to be on a purely empirical base. First studies at the ICB Muenster showed that the sensitivity and selectivity could be changed by many orders of magnitude [143], [144]. One example of a membrane with a certain selectivity towards tetrachloroethene to be deployed in the dry cleaning business is shown in Figure 25. Other examples are shown together with electronic nose developments.

Figure 25. Polymer membrane sensor response against tetrachloroethene. The membrane contains polyethylenoxide, 2-fluorophenyl-2-nitrophenylether, tetraoctylammoniumbromide.

Here the relevant limits of 25 ppm room concentration and 270 ppm in the cleaner before door is opened can easily be detected. Compared with the semiconductor gas sensors, humidity only changes the zero point for the measurements not the slope of the calibration curve. Figure 26 shows the humidity effect on a conductometric ethanol microsensor. Thus any placement of the sensor in a location with similar humidity but zero analyte concentration will correct for that.

Figure 26. Humidity effect on a conductometric polymer gas sensor for ethanol.
Response toward: 350, 500, and 700 ppm ethanol at 10 %, 40 %, and 60 % relative humidity; membrane composition, 54 % polyepichlorhydrin, 36 % o-nitrophenyl-octyl-ether, 10 % tetradodecylammoniumbromide

In order to solve the humidity problem of most gas sensors the ICB Muenster developed and instrument called “Air-Check” in which a

short but efficient pre-sampling on Tenax material takes place. With this the sensitivity could be increased as needed, water no longer interferes and the selectivity could also be increased by analyzing the time course of the rapid thermal desorption step. The whole adsorption – desorption cycle can be performed automatically within less than 1 min!

2.3.1.4. Ion-Selective Field-Effect Transistors (ISFETs)

As described in Section 2.3.1.1, with conventional ion-selective electrodes (ISEs) the ion-selective membrane is placed between the analyte and the internal reference solution. An internal reference electrode makes electrical connection to the internal reference solution, and the measurement system is completed by a second reference electrode in contact with the analyte solution. In any modern pH meter the internal reference electrode is connected to the gate metal of a metal-oxide semiconductor field-effect transistor (MOSFET), which acts as an impedance- converting device (Fig. 27). Normally, a conventional ISE functions very well. However, in certain applications problems can arise due to large size, high cost, and sensitive construction.

These problems might be resolved by the ion-selective field-effect transistor (ISFET). In an ISFET the ion-selective membrane is placed directly on the gate insulator of the field-effect transistor; alternatively, the gate insulator itself, acting as a pH-selective membrane, may be exposed to the analyte solution (Fig. 28). If one compares an ISFET with the conventional ISE measurement system, the gate metal, connecting leads, and internal reference system have all been eliminated. An ISFET is a small, physically robust, fast potentiometric sensor, and it can be produced by microelectronic methods, with the future prospect of low- cost bulk production. More than one sensor can be placed within an area of a few square millimeters. The first ISFETs were described independently by Bergveld [142] and Matsuo, Esashi, and Inuma [145]. The Institute of Microtechnology of the University of Neuchatel is very active in this field [146].

Figure 28. Schematic diagram of an ISFET measuring circuit and cell assembly
a) Reference electrode; b) Ion-selective membrane; c) ISFET

ISFET Operation. The ISFET can be regarded as a special type of MOSFET. To understand the operation of an ISFET it is therefore necessary first to understand the operation of a MOSFET.

An n- channel MOSFET (Fig. 29) consists of a *p*-type silicon substrate with two *n*-type diffusions, the source (c) and the drain (d). The structure is covered with an insulating layer (b), on top of which a gate electrode (a) is deposited over the area between the source and the drain. A voltage is applied to the gate that is positive with respect to both the source and the bulk material. This voltage produces a positive charge at the gate electrode and a negative charge at

the surface of the silicon under the gate. The negative charge is formed by electrons, which are the minority carriers in the substrate, and this in turn creates a conducting channel between the source and the drain. The density of electrons in the channel, and thus the conductivity of the channel, is modulated by the applied gate voltage (V_G). If a constant voltage (V_D) is applied between the source and the drain a change in the conductivity of the channel leads to a change in current between source and drain. The drain current I_D in the unsaturated region ($V_D < V_G - V_T$) of a MOSFET is equal to:

$$I_D = \mu C_{ox} \frac{W}{L} \left[(V_G - V_T) V_D - \frac{1}{2} V_D^2 \right] \quad (15)$$

where

μ = Electron mobility in the channel
C_{ox} = Oxide capacitance per unit area
W/L = Ratio of channel width to length
V_T = Threshold voltage

Figure 29. Schematic diagram of an n-channel MOSFET
a) Gate metal; b) Insulator; c) Source; d) Drain; e) Bulk

A detailed description of the MOSFET is provided in [147].

In an ISFET (Fig. 30) the gate metal is replaced by a selective membrane and an electrolyte solution, or simply by the electrolyte solution, which is in contact with a reference electrode. The potential of the gate with respect to the substrate is the sum of the potentials of the various electronic and electrochemical processes that occur in the external path between the silicon substrate and the gate; i.e., the reference electrode half-cell potential E_{ref}, the solution – membrane or solution – insulator interfacial potential φ_M, and the metal – silicon contact potential. These voltages are added to the externally applied voltages V_g, and the resulting voltage has the same significance and function as that defined in the theory of MOSFET operation. V_{T*}, the threshold voltage of the ISFET, can be described as:

Figure 30. Schematic diagram of an ISFET
a) Reference electrode; b) Ion-selective membrane; c) Insulator; d) Drain; e) Source; f) Bulk

$$V_{T*} = V_T - E_{ref} - \varphi_M \quad (16)$$

From Equation (15) we obtain the following relationship:

$$I_D = \mu C_{ox} \frac{W}{L} \cdot \left[(V_G - V_T + E_{ref} - \varphi_M) V_D - \frac{1}{2} V_D^2 \right] \quad (17)$$

φ_M, the solution – membrane or solution – insulator interfacial potential, depends on the activity of the ions in the analyte solution according to the Nernst – Nikolsky equation [Eq. (6), Section 2.3.1.1] for ISFETs with an additional membrane, or according to a similar equation (see below) for ISFETs with a solution – insulator interface.

If all parameters in Equation (17) apart from φ_M are kept constant, changes in I_D are caused exclusively by changes in the activity of ions in the analyte solution. Thus, in an ISFET, the drain current is modulated by the ionic activity in the analyte solution. A detailed description of ISFET operation is presented in [148].

pH-Sensitive ISFET s. Gate insulators such as Si_3N_4, Al_2O_3, and Ta_2O_3 have been found to be pH sensitive, so FETs in which bare gate insulators of this type are exposed to a solution respond to changes in pH. The pH response can be explained by the "site-binding theory." This model assumes that there are ionizable binding sites present at the surface of an insulator, and that these can exhibit amphoteric behavior with respect to the potential-determining ion (i.e., H^+):

$$A-OH \rightleftharpoons A-O^- + H_S^+$$

$$A-OH + H_S^+ \rightleftharpoons A-OH_2^+$$

According to this model the pH dependence of φ_M is given by the following equation:

$$\varphi_M = 2.3\frac{kT}{q}\left[\frac{\beta}{\beta+1}\right](pH_{pzc} - pH) \quad (18)$$

under the condition that $\beta \gg q\varphi_M/kT$. pH_{pzc} is the pH value for which $\varphi_M = 0$; β is a parameter that reflects the chemical sensitivity of the outer gate insulator, with a value dependent on the density of hydroxyl groups and the surface reactivity. Surfaces with a high β value show Nernstian behavior. For a detailed description of the site-binding model, see [148].

ISFETs Sensitive to Other Ions. Deposition of an ion-selective membrane on top of the gate insulator opens the way to measurement of ions other than H^+. Most of the sensitive materials for ISE applications described in Section 2.3.1.1 have been used in conjunction with ISFETs, providing sensors covering a wide variety of species. Thus, ISFETs with solid membranes have been described with AgCl – AgBr membranes sensitive to Ag^+, Cl^-, and Br^- [149], for example, or with LaF_3 membranes sensitive to fluoride [150]. Ion-sensitive polymer-matrix membranes (liquid membranes with a polymer matrix) have also been used as sensitive membranes for ISFETs. The first experiments involved mainly PVC membranes [151], [152], but these membranes show poor adhesion and poor mechanical strength. To improve membrane adhesion, modified PVC was utilized as a matrix material [153]. The use of silicones as matrix materials has made it possible to prepare very durable ISFETs with polymer-matrix membranes [154]. Other reports describe the use of photopolymerized polymers as matrix materials [155], [156].

Problems. The commercial development of ISFETs has been slow despite intensive research. From the standpoint of broad commercialization the ISFET is in competition with conventional ISEs with respect to price, performance, and reliability, and it is essential that some means be devised for producing ISFETs by commercially acceptable methods. Reaching this stage requires that several problems be solved, however.

ISFETs have so far been used primarily in conjunction with conventional macro reference electrodes. This fact greatly limits the potential benefits to be gained from miniaturization of the sensor. An optimal reference electrode for ISFETs should be miniaturizable and display long-term stability, and it should be subject to fabrication with microelectronic techniques. Attempts have been made to miniaturize macro reference electrodes [157], or to use modified surfaces with extremely low surface-site densities as reference FETs [158], but to date the abovementioned requirements have not been met.

A further problem relates to encapsulation. The ion-sensitive gate area is exposed to the analyte solution, but all other parts of the sensor must be insulated from the solution. In most cases encapsulation is carried out by hand using epoxy resins, but it is impossible to produce ISFETs at low cost by this technique. Both photolithographic methods [159], [160] and an electrochemical method [161] have been proposed for the solution of this problem. One very promising development is the backside-contacted ISFET [162]. The electrical contacts in this case are protected from the analyte solution by means of O-rings, thereby circumventing the need for resins.

As noted previously, ISFETs selective to ions other than H^+ are prepared by deposi-

tion of an additional membrane on top of the gate insulator. If such ISFETs are to be commercialized this membrane must be deposited by a mass-production technique, which will be difficult to achieve with polymer membranes. One possible solution is the development of photolithographically patternable ion-sensitive membranes [163], but such membranes have so far been developed only for a few ions, and problems in the photolithographic deposition of more than one type of membrane on a single chip have not been resolved. The interface between an insulator and a sensitive membrane is also ill-defined in a thermodynamic sense, but this problem was solved by introducing a hydrogel between the sensing membrane and the insulator. Futhermore, ISFETs suffer from drift. The influence of this effect would be eliminated if the sensor were to be used in flow-injection analysis (FIA), so successful applications can be anticipated for ISFETs in the field of dynamic measurement [164].

Only if all the problems cited are successfully resolved will the ISFET live up to the promises that have been held out for it for more than two decades: low cost, multifunctionality, and a robust and reliable construction.

2.3.2. Optical Sensors

2.3.2.1. Fiber-Optical Sensors

The use of optical fibers has become increasingly important in the field of chemical and biochemical sensors. This is clearly due to the fact that fiber-optical sensors combine the strengths of well-known bulk optical analytical methods with the unique advantages of optical fibers. More specifically:

1) An enormous technology base already exists for familiar optical methods of chemical analysis. There is probably no class of chemical analyte that has not at some time been the subject of optical determination through absorption or fluorescence spectroscopy. Methods also exist for labeling a target analyte with an appropriate chromophore or a fluorophore, a common practice in immunoassays.
2) Fiber-optic techniques offer increased sensitivity relative to conventional bulk optic approaches. For example, evanescent wave (EW) spectroscopy is significantly more sensitive than bulk attenuated total reflection spectroscopy. Fiber-optical EW spectroscopy is the only technique suitable for use with highly absorbing or scattering media.
3) The interrogating light in a fiber-optics system remains guided, so no coupling optics are required in the sensor region, and an all-fiber approach is feasible. This represents a sharp contrast to bulk optics, where proper optical adjustment is extremely critical. Fiber optics also provides a good solution to the problem of wide separation between the sensing area and the detector, as in the in vivo monitoring of medical parameters.
4) Recent developments in optical communications and integrated optics have led to optical materials that permit significant miniaturization of the sensing and detecting devices.
5) Since the measurement signal is optical, electrical interference is avoided, and the absence of electrical connectors ensures safe operation in hazardous environments, such as those containing explosive vapors.

Figure 31. Refraction and total internal reflection
n = Refractive index

The light inside an optical fiber is guided by the principle of total internal reflection, as described by Snell's law and depicted in Figure 31. A ray of light striking the interface between two media with differing refractive indices n_1 and n_2 is refracted (ray I) according to the relationship $\sin(\Theta_1)\times n_1 = \sin(\Theta_2)\times n_2$. If the condition $n_1 > n_2$ is fulfilled, total internal reflection will be observed for several angles of

incidence. Thus, at an angle close to the horizontal the incident beam will no longer be refracted into the second medium, but will instead be totally reflected internally at the interface (ray II in Fig. 31). The *critical angle of incidence* $\Theta_c = \arcsin(n_2/n_1)$, which defines the onset of total internal reflection, is determined by the refractive indices of the two media, and whenever $\Theta > \Theta_c$ light is guided inside the medium characterized by n_1.

The general structure of an optical fiber is illustrated in Figure 32. Light entering from the left is confined within the core, which is surrounded by a cladding of lower refractive index (n_{clad}). The whole arrangement is surrounded by a nonoptical jacket, usually made from plastic and designed to provide both stabilization and protection. The fibers themselves can be constructed from a wide variety of transparent materials with differing refractive indices, including various glasses, fused silica, plastics, and sapphire. Most commercially available fibers have glass cores with n_{core} in the vicinity of 1.48 and diameters ranging from 5 – 200 µm; typical claddings have $n_{clad} < 1.48$ and thicknesses of 50 – 1000 µm. An optical fiber is usually characterized by its numerical aperture $NA = (n_{core}^2 - n_{clad}^2)^{1/2}$. The value of NA determines the cone angle Θ_c within which incident light will become entrapped by the fiber, where $\Theta_c = \arccos(NA)$; $\Theta_{max} = \arcsin(NA/n_{env})$ for the cone angle Θ_{max} with which light leaves the fiber at its end (see Fig. 32).

The simple ray-optical description of light-guiding presented above fails to account for several phenomena important with respect to fiber-optical sensors. The most important of these is the *evanescent wave*. The intensity of light that is totally reflected internally does not in fact fall abruptly to zero at the core – cladding interface. Instead, the electromagnetic field intensity decays exponentially as a function of distance from the interface, thereby extending into the medium of lower refractive index. This field is called the *evanescent field*, and its penetration depth d is defined by the distance from the interface within which it decays to a fraction 1/e of its value at the interface. The angle of incidence Θ strongly influences the penetration depth. Values for d vary from 50 – 200 nm, increasing as Θ decreases; d reaches its maximum when Θ is very close to the critical angle.

Figure 32. Structure of an optical fiber
a) Jacket; b) Cladding, $n = n_{clad}$; c) Core, $n = n_{core}$; d) Environment, $n = n_{env}$

Fiber-optical sensors can be constructed in either of two fundamentally different optical configurations with respect to the sensing area. The first is a wave-guide-binding configuration, in which recognition occurs at the surface of the fiber core via the evanescent field. This is achieved by removing the jacket and cladding from the fiber and causing the analyte molecules to bind to the core surface, as in the example described below. Such an arrangement is described as an *evanescent wave sensor* or *intrinsic fiber-optical sensor*. The resulting sensitivity depends greatly on the value of NA [165].

Figure 33. General configuration of an optical detection system for a fiber-optical sensor
a) Source; b) Beam splitter; c) Fiber; d) Sensing area; e) Detector
The excitation system consists of a xenon or tungsten lamp together with a monochromator or optical filter, an LED, or a laser, whereas the light detection system might be a monochromator or filter with a photomultiplier or photodiode.

Alternatively, the fiber-end configuration might be considered, in which analyte is released for recognition purposes into the illuminated space at the end of the fiber. In this case the fiber acts only as a light pipe, resulting in what is known as an *extrinsic fiber-optical sensor*.

Both configurations entail similar optical systems: a spectral light source for excitation (e.g., a xenon or tungsten lamp equipped with a monochromator or optical filter, an LED, or a laser) and a spectral light-detection device consisting of a monochromator or filter to-

gether with a photomultiplier or photodiode. A schematic diagram applicable to the optical systems for these two sensor configurations is presented in Figure 33.

More detailed information regarding the physical principles of fiber-optical chemical and biochemical sensors and the corresponding detection systems is available in [166] and [167].

Biochemical Sensors. Antibodies are widely used as recognition elements in fiber-optical biosensor applications. This is due to the high specificity of the binding reaction between an antibody and an analyte (antigen). To determine this reaction optically, labeling agents such as fluoresceine, rhodamine, or phycoerythrine are used, all of which show absorption and emission bands in the visible region of the spectrum. Linear amplification can be achieved by binding more than one label. Depending on the circumstances, either the antigen or the antibody might be tagged (see below).

The evanescent wave (intrinsic) configuration is most important for biosensors because it permits the antibody or antigen to be immobilized directly on the core surface, and it extends the path for possible interaction between the light and the recognition elements. Accordingly, only tagged molecules inside the evanescent field are subject to excitation. The amount of light energy absorbed, or the light emitted from these molecules and collected by the fiber, gives rise to the measurement signal. In contrast to the extrinsic sensor approach, the intrinsic arrangement therefore reduces noise that would otherwise result from free labeled molecules or intrinsic fluorescence within the environment [167]. Despite these advantages, however, extrinsic biosensors have also been constructed, with binding devices placed in front of the fiber as a way of fixing the recognition elements. These devices can be either glass plates or transparent membranes. This offers the advantage of easy removal and replacement of the recognition elements [168].

Figure 34 provides an example of a biosensor of the intrinsic type. Here the antigen has been immobilized at the fiber core surface where it has been allowed to bind with a labeled antibody. Energy from the evanescent wave is absorbed by the labels, generating a detectable fluorescence signal. Addition of unlabeled analyte to the surrounding solution leads to competition for the binding sites. This permits some of the labeled antibody molecules to diffuse away from the surface, causing the fluorescence signal to decrease. The same general approach is also applicable to immobilized antibodies and tagged antigens [169].

Figure 34. A fiber-optical immunosensor, in which labeled antibody molecules are gradually replaced by free analytes, causing the fluorescence signal to decrease
a) Core; b) Region of evanescent wave
♦ Fixed analyte; ◇ Free analyte; Tagged antibody

Competition between a labeled antigen and an unlabeled analyte can also be effected in an external column, where the labeled antigen has previously been bound to an antibody. Once the competition reaches equilibrium any labeled antigen that has been released can be detected with antibody immobilized on a fiber. In this case the fluorescence signal would be expected to increase with an increased concentration of analyte.

Enzymes are in some cases also useful for recognition and labeling purposes. For example, glucose oxidase has been used to determine glucose on the basis of free oxygen that is consumed, where the disappearance of oxygen is measured with a fiber-optical oxygen subsensor [170]. Labeling of antibodies or antigens with urease or alkaline phosphatase and subsequent addition of a fluoro- or chromogenic substrate leads to detectable production of fluorophores or chromophores. The signal in this case is subject to multiple enhancement since it is proportional to the concentrations of both labeled antigen and antibody as well as to incubation time.

Chemical Sensors. Recognition with a *chemical sensor* is achieved via an analyte-specific reaction involving chemical compounds located inside the sensing area. The reaction must be one that is accompanied by changes in absorbance or fluorescence characteristics. Several examples are described below. A common physical arrangement utilizes a fiber-end approach and two single fibers or two fiber bundles, one for guiding light into the sensing area and the other to carry it away. The chemical reagents are confined within a transparent membrane or a small segment of the fiber itself, near its end and shielded by a membrane.

A particularly wide variety of fiber-optical sensors has been developed for measuring pH values, and many of these sensors are also used as subsensors for other analytes. Sensors for pH determination can be divided into two general types. The first relies on colorimetric acid – base indicators to produce changes in absorbance. For example, the dye phenol red can be copolymerized with acrylamide and bisacrylamide to yield dyed polyacrylamide microspheres. These are in turn packed into a length of cellulose dialysis tubing placed at the end of a pair of fibers that can serve as a vehicle for monitoring changes in absorbance [171]. Bromothymol blue immobilized on styrene – divinylbenzene copolymer has been similarly employed [172]. Alternatively, fluorometric acid – base indicators can be used to detect changes in fluorescence intensity that accompany protonation. Thus, one pH sensor was based on fluorescence quenching by H^+ of the excited state of immobilized fluoresceinamine [173]. 8-Hydroxypyrene-1,3,6-trisulfonate (HPTS) fixed on ethylene vinyl acetate has also been invoked as a fluorescence pH sensor [174].

Chemical sensors for other ions have been reported as well, including the halides and pseudohalides [175]. A sensor of this type is based on the dynamic quenching of fluorescence emission from glass-immobilized, heterocyclic, acridinium and quinolinium indicators. The fluorometric process involved is known to obey the Stern – Volmer equation [176]. Al(III) ions have been determined with morin (3,5,7,2′,4′-pentahydroxyflavone) [177]. Thus, aluminum displaces the hydrogen ion when it binds to morin, leading to a change in fluorescence properties. Be(II) has also been determined using morin [178]. Furthermore, reports have appeared on sensors for Mg(II), Zn(II), and Cd(II) based on quinoline-8-ol sulfonate immobilized electrostatically on an anion-exchange resin [179].

Gas sensors for carbon dioxide [180] and ammonia [181] in aqueous solution have been constructed on the basis of a gas-permeable membrane and an optical pH subsensor. Gases diffusing through the membrane produce a change in the pH in the sensing region of a fiber-optical pH sensor. Sulfur dioxide [182] and oxygen [183] sensors take advantage of the quenching of the energy transfer (Förster transfer) between excited pyrene and perylene, both of which can be immobilized on a silicone matrix. Other O_2 sensors rely on the effect of fluorescence quenching as described by the Stern – Volmer equation. These generally involve metal complexes like tris(2,2′-bipyridine)ruthenium(II) [184]. In most cases fluorescence quenching also leads to a shortening of the fluorescence lifetime, which can be determined, for example, by phasesensitive detection [185]. The advantage of this method is that fluorescence lifetime is independent of the fluorophore concentration, and there is no signal drift due to bleaching.

2.3.2.2. Integrated Optical Chemical and Biochemical Sensors

Generally speaking, integrated optical devices can be constructed using techniques similar to those for manufacturing semiconductor devices. This offers great potential for cost reduction and facilitates the miniaturization often required in sensor applications. Furthermore, such sensors retain all the advantages of the well-known fiber-optical sensors.

The propagation of a light ray confined within a planar dielectric film (or *waveguide*) is depicted in Figure 35. Guidance of the light is possible only if total internal reflection occurs at the interfaces film – cover (I) and film – substrate (II). This condition is met if the refractive index of the film n_f is greater than that of both the cover n_c and the substrate n_s. Moreover, the angle of incidence Θ must be greater than the critical angles for total internal reflection at the interfaces I (Θ_{cI}) and II (Θ_{cII}), given by the expressions $\sin(\Theta_{cI}) = n_c/n_f$ and $\sin(\Theta_{cII}) = n_s/n_f$. To fulfill

the self- consistency condition within the waveguide, the phase shift of the light wave as it travels from point 1 to point 3 must be an integral multiple m of 2π, where m is called the *mode number*.

$$\left(\frac{2\pi}{\lambda}\right)\cdot L\,(n_{\mathrm{f}},h,\Theta)+\Phi_{\mathrm{I}}\,(n_{\mathrm{f}},n_{\mathrm{c}},\Theta)$$
$$+\Phi_{\mathrm{II}}\,(n_{\mathrm{f}},n_{\mathrm{s}},\Theta)=2\pi m \qquad (19)$$

Figure 35. Propagation of a confined light ray within a planar waveguide mounted on a substrate
Most substrate materials are glasses or crystals with a refractive index of 1.4 – 2.4, and the cover material is air; the thickness of the film ranges from 0.1 to several micrometers.
a) Cover, $n=n_{\mathrm{c}}$; b) Film, $n=n_{\mathrm{f}}$; c) Substrate, $n=n_{\mathrm{s}}$

Φ_{I} and Φ_{II} are the phase shifts caused by reflection at the interfaces I and II, and $(2\pi/\lambda)\,L$ is the shift accompanying travel along the optical path $L=2\,h\cos(\Theta)$. The values of $n_{\mathrm{f}}, n_{\mathrm{c}}, n_{\mathrm{s}}$, and m are usually fixed by the fabrication process for the waveguide, and λ is established by the light source. The value of Θ can therefore be calculated from Equation (19). It is useful to define an *effective refractive index* n_{eff} for the guided mode, defined as $n_{\mathrm{eff}}=n_{\mathrm{f}}\sin(\Theta)=n_{\mathrm{eff}}\,(n_{\mathrm{f}},n_{\mathrm{c}},n_{\mathrm{s}},h,m,\lambda)$, which, apart from λ, depends only on the material and geometric parameters of the waveguide. The parameter n_{eff} can be used to treat all types of light-propagation effects within the waveguide.

Even though light is totally reflected internally at the interfaces, its intensity does not fall to zero outside the waveguide. Just as with optical fibers, the small part of the guided light located outside the waveguide is referred to as the evanescent field, with a penetration depth ranging from 100 – 300 nm depending on the waveguide performance. A more detailed mathematical treatment of planar and strip waveguides is presented in [186].

Waveguides intended as chemical or biochemical transducers can be operated in either of two modes. A comprehensive physical description of these operating modes and the corresponding efficiencies is provided in [187].

First, it is possible to use a waveguide for acquiring refractive index data. This can be accomplished by coating the waveguide with a reactive but transparent chemical layer of a thickness greater than the penetration depth of the evanescent field. In this case the layer can be treated as if it were a cover material. Any chemical reaction with the layer will result in a change in the refractive index n_{c}, which in turn leads to a change in the effective refractive index n_{eff}. This approach has been used successfully in the production of sensors for CO_2 and SO_2 [188].

Figure 36. Specific antibody – antigen binding at the surface of a planar waveguide, causing the thickness of the adlayer to change
a) Cover, $n=n_{\mathrm{c}}$; b) Film, $n=n_{\mathrm{f}}$; c) Substrate, $n=n_{\mathrm{s}}d_1$, d_2 = Layer thicknesses before and after binding

The adsorption and desorption of molecules is depicted in Figure 36 as an example of the second operational mode. The waveguide in this case is coated with a thin chemical layer consisting, for example, of an antibody. When the antibody – antigen binding reaction occurs, the effective thickness [187] of the entire waveguide increases, which again causes a change in the effective refractive index of the guide. Direct immunosensors based on this method have often been reported in the literature [189], [190].

Detecting a change in n_{eff} is a problem that can be solved in various ways. An interferometer approach analogous to the Mach – Zehnder interferometer [191], [192], the Fabry – Perot interferometer [188], or the difference interferometer [193] has often been used. The general arrangement of a Mach – Zehnder interferometer is illustrated in Figure 37 A. The diameter of the strip waveguide is usually on the order

of 5 µm, with a distance between the two arms of < 1 mm, and a total length for the device of < 3 cm. Only the signal arm with its reactive chemical layer is exposed; the reference arm is covered by a dielectric film with a refractive index lower than that of the waveguide. The output power P_{out} of the device depends on the extent of the light phase shift $\Delta\Phi = (2\pi/\lambda)\, L\, n_{\mathrm{eff}}$ between the signal arm and the reference arm; e.g., $P_{\mathrm{out}} = P_{\mathrm{in}} \cos^2(\Delta\Phi/2)$.

Figure 37. General arrangement of a Mach – Zehnder interferometer (A) and an input grating coupler (B)
In A only the signal arm is exposed to an active chemical layer while the reference arm is covered, whereas in B the grating is provided with an active layer and exposed to the sample.
a) Input beam; b) Output beam; c) Incoupled beam

Grating couplers can also be used to determine the value of n_{eff}, as depicted schematically in Figure 37 B. For efficient light *incoupling* the angle α must be consistent with the expression $n_{\mathrm{eff}} = n_0 \sin(\alpha) + l\,(\lambda/\Lambda)$, where l is the diffraction order and Λ the grating period. According to this relationship, a change in n_{eff} leads to a change in the angle α that will reinforce light guided within the waveguide. A grating coupler can also be used in an *outcoupling* arrangement. In this case it is the angle for the outcoupled light that would conform to the grating equation. A detailed description of grating- coupler methods is presented elsewhere [194].

2.3.2.3. Surface Plasmon Resonance

Transducers for optical sensing systems in chemical and biochemical sensors have also been developed based on the sensitivity of surface plasmon resonance (SPR) devices. Since first described in 1983 [195], SPR transducers have been used in many different applications, including immunoassays [195], [196] and sensors for gases [195], [197] and liquids [198].

Electron charges located at a metal – dielectric interface can be caused to undergo coherent fluctuations known as *surface plasma oscillations* or *surface plasmons* (SP). The frequency ω of such longitudinal oscillations is related to the wave vector $\boldsymbol{k}_{sp}$ *by the dispersion relationship.*

$$k_{\mathrm{sp}} = \left(\frac{\omega}{c}\right) \cdot \sqrt{\frac{e_{\mathrm{M}} \cdot e_{\mathrm{D}}}{e_{\mathrm{M}} + e_{\mathrm{D}}}} \tag{20}$$

where $\varepsilon_{\mathrm{M}}(\omega)$ is the permittivity of the metal and $\varepsilon_{\mathrm{D}}(\omega)$ that of the surrounding dielectric (cf. Fig. 38); c is the velocity of light in a vacuum. The permittivity of the metal ($\varepsilon_{\mathrm{M}} = \varepsilon_{\mathrm{M1}} + \mathrm{i} \cdot \varepsilon_{\mathrm{M2}}$) is complex and the value of $\varepsilon_{\mathrm{D}} = n_{\mathrm{D}}^2$ is real, where n_{D} is the refractive index of the dielectric. A surface plasmon can be excited only if the conditions $\varepsilon_{\mathrm{M1}} < 0$ and $-\varepsilon_{\mathrm{M1}} - > \varepsilon_{\mathrm{M2}}$ are fulfilled. For example, gold, silver, and palladium are potentially applicable metals with negative values of $\varepsilon_{\mathrm{M1}}$ for frequencies corresponding to visible light [199].

Figure 38. Attenuated total reflection coupler used to excite surface plasmons at the metal – dielectric interface; excitation is observed as a minimum in the intensity of the reflected light by scanning the angle of incidence
a) Prism; b) Metal; c) Dielectric

SP excitation can be accomplished in several ways. A very simple and often used approach is illustrated in Figure 38. RATHER [199] has described this as the *attenuated total reflection* (ATR) coupler. Here the base of a prism is coated with a thin metal film approximately 50 nm thick. Incident monochromatic light is reflected at this interface in such a way that a projection of the light vector $\boldsymbol{k}_0$ on the interface becomes $\boldsymbol{k}_{\mathrm{x}} = \boldsymbol{k}_0\, n_{\mathrm{p}} \sin(\Theta)$. If the resonance (Re) condition $\boldsymbol{k}_{\mathrm{x}} = Re\{\boldsymbol{k}_{\mathrm{sp}}\}$ is fulfilled, the evanescent field of the incident light excites an SP at the metal –dielectric interface, although this is only possible with light polarized parallel to the plane of incidence (p-polarized). The excitation

is observed as a sharp minimum in the intensity of the reflected light, and it can be detected by scanning the incident angle.

Using such an ATR device, small changes in $\varepsilon_D = n_D^2$ and the build-up of a thin layer at the metal – dielectric interface can easily be detected by measuring the shift in the *resonance angle* Θ.

For an immunosensing application the metal layer would be coated with appropriate antibodies, either immobilized covalently or embedded into a matrix layer. Upon exposure to a specific antigen the resonance angle should shift relative to that observed in an analyte-free environment due to the increase in layer thickness that accompanies binding of the analyte. For example, a thickness change of 0.1 nm results in a 0.01° change in the resonance angle, a shift that can be measured quite accurately (see also Section 3.3.1).

If an ATR device is to be used for chemical sensing, the metal surface must be coated with a thick dielectric layer of a reactive chemical. Chemical reaction within the layer then produces changes in n_D that can be detected by the corresponding shift in Θ.

2.3.2.4. Reflectometric Interference Spectroscopy

Gauglitz introduced reflectometric interference spectroscopy (RIFS) into the field of chemical and biochemical sensing [200], [201]. Figure 39 shows the underlying optical principle. The interference of the schematically shown partial light rays 2 and 3 leads to an intensity modulation of the overall reflected light spectra. This must be happening within the so-called coherence length of light after leaving the substrate. The coherence length of light using, e.g., a tungsten light bulb in the wavelength range of 400 – 1000 nm is about 20 µm. Therefore, the thickness of the interference causing layer has to be less than 20 µm and has to exceed the wavelength of the used light to give a measurable interference pattern. A layer thickness between of 0.5 and 10 µm with $n_2 \approx 1.4$ fits well this demand.

Light rays which undergo multiple reflections at the different interfaces contribute little because of their lower intensity. The scattered light should be as low as possible as with light from other sources. The equation for the interference pattern is:

$$I_{\text{all}}(\lambda) = I_1 + I_2(n_2) + I_3(n_2) + 2\cdot(I_2(n_2)\cdot I_3(n_2))^{1/2}\cdot \cos\{(4\pi/\lambda)\cdot(n_2\cdot d)\} \quad (20a)$$

Figure 40 shows a typical interference pattern after an alteration of the refractive index and the thickness of the interference layer. The shift $\Delta\lambda$ is caused by Δd and Δn_2 whereas the chance in the modulation depth Δg is caused by Δn_2 only.

Thus, the basic response of an RIFS based polymer or immunosensor is the alteration of the optical pathway. For the evaluation of the interference pattern several algorithms have been developed. After the determination of the minima and maxima the interference order k is determined using a series of calculations and curve

Figure 39. Schematic sketch of the principles of RIFS in a flow through set-up. Schematically shown light rays I_2 and I_3 can be re-collected with a fiber optic and lead to a monochromator with a CCD detector.

fitting techniques using newly developed software. Before a measurement is carried out a reference spectrum is obtained from an uncoated sensor including all spectral information except for the interference pattern. All further spectra obtained are divided by the reference spectrum to obtain the natural interference pattern.

Figure 40. Observed interference pattern of RIFS normally recorded via a CCD array; comprehensive software [202] is needed to gain the needed information from this spectrum

2.3.3. Mass-Sensitive Devices

2.3.3.1. Introduction

Mass changes are usually detected with the aid of a gravimetric device, such as a balance. Ideally, balance sensitivity can be extended down into the microgram range, but the desire for further improvements in sensitivity and miniaturization of the experimental setup has led to the development of other mass-sensitive devices: the so-called quartz microbalance (QMB), which is the best-known system, and other, more recent devices such as the surface acoustic wave oscillator (SAW), the Lamb wave oscillator (LW), and the acoustic plate-mode oscillator (APM), which represent the present state of the science (Section 2.3.3.2). These devices are all based on the *piezoelectricity* of solids, (see Section 2.3.3.3), a phenomenon that permits the generation of vibrations or the propagation of waves. A piezoelectric substrate, usually a quartz plate, is stimulated to vibration by an oscillating electric circuit. This corresponds to an interconversion of electrical and mechanical vibrations (deformations of the crystal), resulting in a device that can be regarded as either an oscillator or a resonator.

Bulk waves, surface waves, and waves of other types (see Section 2.3.3.3) are associated with characteristic resonance frequencies corresponding to the most stable frequencies of vibration. Such a resonance frequency is itself highly dependent on the mass of the oscillating plate. A slight change in the mass of the plate will result in a considerable change in the resonance frequency, which can be measured very accurately. An oscillator of this type can therefore be used as a mass-sensitive transducer. Other factors that may influence the observed frequency shift include changes in the viscosity and density of surface layers as well as such physical parameters as forces, temperature, and pressure.

To construct a mass-sensitive sensor the surface of a piezoelectric material must be coated with an appropriate chemically or biochemically reactive layer capable of interacting with the proposed analyte and – ideally – recognizing it as well (see Section 2.3.3.4). Such an interaction causes the mass of the crystal to increase, resulting in a measurable shift in the resonance frequency. A relationship thus exists between the amount of analyte adsorbed or absorbed and the frequency shift of the oscillating system. Resonance frequency changes can be established very accurately, so very small changes in mass can be detected. A theoretical approach applicable to simple cases is described in [203].

To date, mass-sensitive devices have been used mainly for sensing analytes in the gas phase; they are also applicable in principle to liquids, but this presupposes a more sophisticated physical arrangement, a much more complicated signal control, and very careful interpretation. Many published papers have dealt with the potential use of QMB, SAW, and, more recently, APM and LW devices as mass-sensitive detectors in chemical and biochemical sensors, but no such device has yet established itself commercially – with the exception of QMBs employed for thin-layer thickness measuring, which cannot be regarded as chemosensors in the strictest sense of the term [204].

Historical Development. The first report concerning the use of piezoelectric resonance from a quartz crystal in a gravimetric microbalance is by J. Strutt (Lord Rayleigh), who in 1885 described a shift in resonance frequency accompanying an infinitesimal mass change in a mechanical oscillator [205]. Fundamental studies into the mass sensitivity of quartz resonators

Figure 41. Selected applications of piezoelectric transducers with respect to both the direct piezoelectric effect (active transducer) and the converse piezoelectric effect (passive transducer) [222] (with permission from Springer-Verlag, Heidelberg)

and their potential application for measuring the thickness of thin layers were reported in 1959 by SAUERBREY [203], [206]. KING was the first to use a quartz microbalance "QMB" (in 1964) as a gas-phase detector in an analytical application [207], [208]. Numerous more recent papers discuss the fundamentals [209–216] and applicability [217–220] of bulk acoustic wave (BAW) piezoelectric resonators as chemical and biochemical sensors in the gas phase as well as in liquids, but physical devices for the measurement of pressure, temperature, or distance have attracted greater commercial interest [221], [222]. Nevertheless, quartz microbalances based on bulk acoustic waves do find frequent use in analytical research and development.

RAYLEIGH in an early paper [205] also noted the existence of waves that are propagated only in relatively thin surface layers, but it was not until 1979 that WOHLTJEN and DESSY adapted these so-called surface acoustic waves (SAWs) for incorporation into a chemical gas sensor [223–225]. The chief advantages of SAWs are increased sensitivity relative to BAWs of lower resonant frequencies and a greater potential for miniaturization. On the other hand, SAWs are associated with a variety of circuitry problems resulting from the relatively high operating frequencies required for adequate sensor sensitivity. A modification of this type of wave was introduced by CHANG and WHITE [226], [227], who adapted a SAW sensor by creating an exceptionally thin membrane-like piezoelectric region in the substrate directly beneath the acoustic path. This in turn led to the production of *Lamb waves*, which proved to be particularly suitable for chemical sensor applications, opening the way to the so-called plate-mode oscillator, a device representing the present state of the art.

2.3.3.2. Fundamental Principles and Basic Types of Transducers

Solids and other vibrationally active mechanical structures are capable of being stimulated by electrical, thermal, or optical means either to vibration or to the further propagation of waves. Piezoelectric solids, preferably quartz (SiO_2), are especially susceptible to emission and reception of mechanical vibrations and waves. The anisotropic nature of quartz supports various types of waves, each with its characteristic frequency, amplitude, and propagation properties.

Survey of the Different Types of Piezoelectric Substrates. A summary of the various types of transducers involving piezoelectric solids, including their chemical and physical applications, is presented in Figure 41. Acoustic gravimetric sensors can be categorized generally on the basis of their design, their wave mode (BAW, SAW, APM, LW), and their frequency

range. Figure 42 offers a schematic overview of the principles and design characteristics of various piezoelectric transducers. Criteria for establishing the usefulness of a particular vibrational system for the determination of mass include [209]:

1) The system should be readily excitable, preferably by electrical means
2) The system must lend itself to coupling with a frequency- (or period-) measuring device without significant disturbance
3) The system must be associated with sharply defined resonant frequencies so that the frequency (or period) of vibration can be determined precisely within a reasonably short period of time
4) In order to provide the required mass sensitivity, the mass-induced change in resonant frequency must be greater than the instability level of the resonant frequency and such uncertainties in the frequency (or period) as may accompany the measurement technique employed
5) Resonant frequency changes due to environmental disturbances (e.g., fluctuations in temperature or pressure, the presence of electrical or magnetic fields, or external mechanical stress) must be small relative to those caused by mass changes
6) An equation must be available in analytical form relating mass changes to the corresponding shifts in resonant frequency

Bulk Acoustic Wave Transducers. Waves of the bulk acoustic type (BAWs) can be invoked for microgravimetric applications through the use of either AT- or BT- cut plates derived from a single crystal of α-quartz, where "AT" and "BT" refer to cuts with specific orientations relative to the main axis of the crystal (see below and [229]). Figure 43 A represents a schematic diagram of such a quartz crystal with its associated electrodes and sensing layers. This diagram also indicates how a species to be detected might be absorbed into the sensing layer. Both sides of the quartz are in contact with electrodes. The corresponding electrodes are usually 300 – 1000 nm thick and 3 – 8 mm in diameter, and are made of gold, nickel, silver, or aluminum [217]. Introduction of oscillating electrical energy through an appropriate electrical circuit causes the mechanical structure to begin vibrating. In the case of AT- cut quartz the crystal vibrates in the thickness shear mode, as shown in Figure 43 B (see also Fig. 58).

Figure 42. Schematic overview of acoustic gravimetric devices, illustrating the principles of wave propagation and design [228] (with permission from VDE-Verlag, Berlin) A) BAW; B) SAW; C) APM; D) LW substrates

Theory. Microgravimetric application of acoustic devices presupposes a quantitative relationship between an observed relative shift in the resonance frequency and an added mass. In the case of a quartz plate vibrating in a liquid an extended approach is required with respect to changes in the viscosity and density. The first useful relationship of this type was developed by SAUERBREY, who treated the added mass as an "added thickness" of the oscillator. The relationship itself was based on a quartz crystal vibrating in its thickness shear mode in the gas phase (Fig. 44). The observed oscillation frequency (f_q) is inversely proportional to the thickness t_q of the crystal; $f_q = N/t_q$, where N is a frequency constant ($N = 0.168$ MHz cm for AT- cut quartz at room temperature). The mass

of the crystal is $m = \varrho A t_q$, where ϱ is the crystal density and A its cross-sectional area. In this derivation the mass increment due to a foreign mass Δm is treated as an equivalent change in the mass of the crystal. Invoking the approximation $\varrho_q = \varrho_f$ leads to the equation:

$$\Delta f_q = -f_q \frac{\Delta m}{m} \tag{21}$$

which finally provides the following expression for an AT- cut crystal:

$$\Delta f_q = -2.3 \times 10^6 f_q^2 \frac{\Delta m}{A} \tag{22}$$

where f_q is expressed in megahertz, Δm in grams, and A in square centimeters. Since f_q for a quartz crystal is typically 10 MHz, and a frequency change of 0.1 Hz can be readily detected by modern electronics, it is possible in this way to detect mass changes of as little as about 10^{-10} g/cm^2 in the gas phase (!) [230].

Figure 43. Schematic diagram of a quartz crystal augmented with electrodes and sensing layers, illustrating the way in which the species to be detected is absorbed into the sensing layer (A) and the ideal thickness shear mode of a quartz plate (B) [230], [203]
a) Quartz crystal; b) Electrodes; c) Sensing layers x, y, z = Coordinates of the quartz plate; X, Y, Z = (IEEE-standard) coordinates for a single crystal of α-quartz, where X is the polar axis and Z is the optical axis; t_q = Thickness of the quartz plate, where the wavelength $\lambda = 2\,t_q$; ξ = Shear amplitude; ϑ = Angle of rotation

Lu has developed a model involving propagation velocities for sound waves in the substrate (for quartz, v_q) and in the sensing layer (v_f) [216]. Reflection and refraction occur at the interface between the crystal (q) and the film (f) (Fig. 44) analogous to the optical reflection and refraction observed at a boundary between two materials with different optical densities. The shear velocities in the quartz crystal and the film coating, respectively, are:

$$\text{quartz } v = \sqrt{\frac{\mu_q}{\varrho_q}}\,\text{q} \tag{23}$$

$$\text{film } v = \sqrt{\frac{\mu_f}{\varrho_f}}\,\text{f}$$

Figure 44. Shear wave (with permission from Plenum Publishing, New York)
A) In a quartz crystal; B) After an incremental increase in the crystal thickness; C) With the addition of a film m_q, t_q = Mass and thickness of the quartz; m_f, t_f = Mass and thickness of the film

Given a knowledge of the shear moduli μ_f and μ_q, Equation (23) can be used to calculate the shear velocity of the wave. Ideal wave-propagation behavior is observed with a crystal upon which such a film has been deposited provided there is a negligible amount of frictional loss. In this case the resonance condition is valid, which leads to Equation (24):

$$\tan\left(\frac{\pi \cdot f_c}{f_q}\right) = \left(\frac{\varrho_f \cdot v\text{f}}{\varrho_q \cdot v\text{q}}\right) \tan\left(\frac{\pi \cdot f_c}{f_f}\right) \tag{24}$$

where $f_c = \omega/2\pi$ is the resonance frequency of the crystal upon which material has been deposited. The terms $\varrho_f \cdot v_f$ and $\varrho_q \cdot v_q$ are the acoustic impedances Z_f and Z_q of the film and crystal, respectively. Their ratio, $Z = Z_f/Z_q$, is an important parameter with respect to acoustic

matching of the materials. For optimum resonance conditions Z should be as close as possible to unity, because its value affects the resilience of the whole assembly, and maximum stability corresponds to $Z \sim 1$ [231].

For example, Z has a value of 1.08 for a piezoelectric crystal covered with aluminum electrodes (shear-mode impedance of SiO_2: $Z_{SiO^2} = 8.27 \times 10^6\ \mathrm{kg\,s\,m^{-2}}$; that of Al: $Z_{Al} = 8.22 \times 10^6\ \mathrm{kg\,s\,m^{-2}}$), indicative of the good match associated with this material combination. Deposition of gold electrodes on an SiO_2 surface leads to a Z-value of 0.381, which is barely acceptable (shear-mode impedance of gold: $Z_{Au} = 23.2 \times 10^6\ \mathrm{kg\,s\,m^{-2}}$) [231].

From a practical point of view it is important to develop a relationship involving more experimentally common parameters influencing the frequency response. The frequency response of a piezoelectric sensor in the presence of a gas at a particular pressure can be related generally to three effects: the hydrostatic effect (p), the impedance effect (x), and the sorption effect (m):

$$-\frac{\Delta f}{f_0} = \left(\frac{\Delta f}{f}\right)_p + \left(\frac{\Delta f}{f}\right)_x + \left(\frac{\Delta f}{f}\right)_m \tag{25}$$

For gravimetric measurements and sensor applications, the latter effect (that is, to added mass) is the most important, and the other two effects can be viewed as nonspecific interferences. Because both of these terms are three orders of magnitude smaller than the mass term, the mass relationship alone is sufficient for characterizing measurements in the gas phase. However, situations do exist in which the other two effects cannot be ignored. For instance, if the pressure is changed from that of the surrounding air to a vacuum the first term is no longer negligible, and in the case of liquids any change in viscosity or density alters the impedance, so this term must be taken into consideration.

Other theoretical approaches relevant to applications in the gas phase and dealing with thickness-shear mode acoustic wave quartz sensors are presented in [213], [232–237].

Bulk Acoustic Waves in Liquids. When a quartz crystal is placed in a liquid, there is a significant change in both the density and the viscosity of the surrounding medium. Both become much larger than in the gas phase, and the consequences must be taken into account with respect to the second term in Equation (25). Thus, the Sauerbrey equation is no longer applicable if the viscoelastic properties of the contacting medium (liquid and/or film) change during the course of an experiment. The liquid now represents an additional mass load, which produces coupling between the substrate elastic shear wave and the liquid. Kanazawa derived the first theoretical relationship linking the properties of a liquid to the frequency response of a piezoelectric crystal. In a liquid medium, the shear motion of the crystal causes motion to occur in the adjacent layer of solvent molecules (usually water). Up to a layer thickness of approximately 1 µm the solvent molecules move with a certain degree of "slip," which corresponds to a phase shift in the third and subsequent layers. Therefore, vibrational energy from the oscillator is continuously dissipated into the liquid. If only one side of the crystal is coupled to the liquid, the result is a standing wave perpendicular to the substrate surface. For liquids with Newtonian behavior this wave can be described theoretically as a damped wave. As is usual for this type of wave, a decay constant k is used to describe the magnitude of the damping. In this case the constant k can be related to $(\omega/2\,\nu)^{1/2}$, where ν is the kinematic viscosity. The damping distance (limit of wave propagation) is on the order of micrometers, while the frequency shift can be expressed [238] as:

$$\Delta f = f_0^{3/2} \left(\frac{\nu}{\pi \mu_q \varrho_q}\right)^{1/2} \tag{26}$$

Figure 45 shows the effect of microscopic kinematic viscosity at the crystal – liquid interface, where the magnitude of the observed frequency shift has been plotted against the corresponding increase in density for a glucose solution.

The frequency shift for quartz is highly dependent on changes in the viscosity and density of a surrounding liquid. This situation can be discussed in a straightforward way on the basis of the *quartz equivalent circuit* [231], [239], shown in Figure 46, which consists of the following elements:

1) The $L' - C'$ combination, which determines the resonance frequency f_m of the motional arm
2) A parallel capacitance C_p, caused by the electrodes on the quartz and any stray capacitance

3) A resistive component R'

Figure 45. The effect of kinematic viscosity on resonance frequency as a function of glucose concentration (in water) for a 5-MHz quartz crystal
——= Calculated; • = Measured (with permission from Am. Chem. Soc., Washington)

The resistance R' is a measure of mechanical losses from the vibrating quartz, and it therefore reflects the viscoelastic properties of the contacting liquid [240], [241] or a deposited film [242]. Surface roughness also influences the value of R' [243]. This is often not considered in certain applications. It is highly unlikely that in the case of a directly sensed immuno-surface-reaction the binding events are uniformly smeared out. Likewise, immobilized peptide molecules may alter the tertiary shape by changing the ionic strength, resulting in a different surface roughness. Changes in the vibrating mass correspond to changes in the self-inductance L' [244], [245]. Thus, the resonance frequency of the motional arm (f_m; see Fig. 46) changes in proportion to the mass. In deriving Equation (26) KANAZAWA considered only those L' values for the motional arm that contribute to a frequency shift, but in a real experiment any change in $\Delta R'$ is normally accompanied by a change in L' (typical values for R' in air and in water are $7\,\Omega$ and $350\,\Omega$, respectively, for a 6 MHz quartz crystal). Thus, when a quartz crystal is immersed in liquids of different viscosities, both L' and R' can be expected to vary. Use of an impedance analyzer makes it possible to determine the increase in R' associated with operation of a quartz crystal in air versus a liquid. The frequency shift of the motional arm can be calculated from the values of C' and L' using the formula [239]

$$f_m = 1/[2\pi(L'\,C')^{1/2}].$$

SAW Transducers. Surface acoustic wave (SAW) sensors have been designed with sensitivity to many different physical quantities, including force, acceleration, hydrostatic pressure, electric field strength, dew point, and gas concentration [246]. The operating principle of an SAW for use with gases is conceptually quite simple. A surface acoustic wave – a periodic deformation perpendicular to the material surface – is transmitted across the surface of some appropriate solid that has been exposed to the atmosphere subject to analysis. With a homogeneous substrate, usually a piezoelectric solid

like quartz or $LiNbO_3$, the required SAW (sometimes also called a Rayleigh wave) is generated by means of an interdigital transducer (IDT).

In contrast to a quartz microbalance, the requisite IDT components are deposited only on one side of the crystal. These take the form of planar, interleaved, metal electrode structures, (with permission from Plenum Publishing, New York) where adjacent electrodes are supplied with equal but opposite potentials (Fig. 47). Application of a time-varying r. f. potential causes the crystal to undergo physical deformations, and if these are confined to the surface region of the crystal, the result is a surface acoustic wave (Fig. 47 B) [248]. Such vibrations will interfere constructively only if the distance $L/2$ between two adjacent "fingers" (see Fig. 37 A) is equal to one-half the elastic wavelength. The frequency $f = v_R/L$ that corresponds to such a cumulative effect is called the *synchronous frequency* or *resonance frequency* (f) [230].

The waves that are generated have their mechanical and electrical components in a single plane, the *sagittal* plane, which is perpendicular to the substrate surface. The phase velocity (v_R) and the amplitude (A) of an SAW are determined by elastic, piezoelectric, dielectric, and conductive properties of the substrate as well as by its mass. If one of these parameters can be modulated in an appropriate way by the quantity of interest, a sensing device can be constructed. Such a modulation could be induced in the transducer itself and/or in the transmission region (waveguide or *delay line*). With layered substrates the physical properties of each layer as well as the thicknesses of the layers determine the phase velocity and the amplitude of the resulting SAW [230]. Various energy-loss mechanisms also operate on the propagating SAW: scattering loss due to finite grain size, thermoelastic loss due to nonadiabatic behavior of the acoustic conductor, viscous loss caused by the dissipation of energy in a direction perpendicular to the transducer – environment interface, and hysteresis absorption due to irreversible coupling between SAW energy and an adsorbate [231]. Any addition of mass during the sensing step may change the magnitude of one or more of these phenomena, and may also lead to changes in v_R and A, especially a frequency shift (Δf) or a relative frequency shift ($\Delta f/f$). An exact description of the physical processes involved in the generation, propagation, and detection of SAWs is complex, and is available from such sources as [248], [249].

Figure 47. Interdigital metal pattern of a uniform transducer; the IDT behaves like a sequence of ultrasonic sources or receivers [247]
A) An SAW device with input and output transducers; B) A uniform transducer defined by half-spatial period L, electrode width d, and aperture width W; the observation line P used for derivation of the impulse response is at a distance $z + L$ from the first source; C) Schematic diagram of an SAW sensor with a transmitter T, a receiver R, and a chemically selective layer deposited in the form of a delay line [231] (with permission from Plenum Publishing, New York)

The considerations presented above provide the basis for using SAWs in gas-monitoring devices, because observed frequency shifts are pro-

portional to added mass. However, the characteristic frequency of an SAW is also sensitive to changes in temperature or pressure. The ideal substrate would be one with a zero temperature delay coefficient but a high piezoelectric coupling effect. Despite extensive materials research efforts, it is currently necessary to choose between these parameters; e.g., ST- cut quartz is the preferred substrate if a zero temperature coefficient is most important, and cuts of lithium niobate are selected for high piezoelectric coupling.

Figure 48. Various possible sensor configurations for SAW chemical sensors [230]
A) Single delay line; B) Dual delay line; C) Three-transducer device; D) Resonator
i = Input transducer; o = Output transducer

Sensor Configurations. A single SAW sensor may sometimes suffice for a gas sensing application (Fig. 48 A), but often the sensors display undesirable sensitivity to such effects as temperature, pressure, and ambient humidity. Overcoming these problems requires the establishment of a relative signal output. For example, VETELINO et al. have described a dual-line SAW gas sensor [230], [250], [251]. One delay line in this case is used for measuring, while the other acts as a reference (see Fig. 48 B). The advantage of a dual delay-line configuration is that it transforms the output signal into a relative change in oscillator frequency, which can be attributed only to the effects of the analyte. D'AMICO et al. have described a system based on a three-transducer delay line (see Fig. 48 C). This device also has two dual-delay lines, but the paths are established in this case by one input IDT and two output IDTs. Again, one path of the delay line is coated and the other remains uncoated as a way of minimizing the effects of both temperature and pressure [252].

The first use of an *SAW resonator* sensor was reported by MARTIN et al. [253]. The corresponding resonator incorporated a single IDT located between two acoustically reflecting mirrors. The distance between the mirrors was so adjusted as to ensure constructive interference between successive reflections, resulting in a maximum for one particular frequency (Fig. 48 D).

Theory. The SAW velocity v_{R} can be affected by many factors, each of which is associated with a potential sensor response:

$$\frac{\Delta v}{v_{\mathrm{R}}} = \frac{1}{v_{\mathrm{R}}}\Big(\frac{\partial v}{\partial m}\Delta m + \frac{\partial v}{\partial c}\Delta c + \frac{\partial v}{\partial \sigma}\Delta\sigma + \frac{\partial v}{\partial \varepsilon}\Delta\varepsilon + \frac{\partial v}{\partial T}\Delta T + \frac{\partial v}{\partial P}\Delta P + \dots\Big) \tag{27}$$

where v_{R} is the phase velocity unperturbed by such external factors as m, c, σ, and ε (the mass, elastic constant, electrical conductivity, and dielectric constant of the solid medium, respectively), as well as T and p, the environmental temperature and pressure [246]. Three types of films have been considered for use as reactive layers:

1) Nonconductive isotropic overlay film
2) Electrically conducting overlay film
3) Metal-oxide semiconducting film

A theoretical treatment can be developed for each of these film types with respect to its properties, involving, in the nonconductive case, the thickness t_{f}, the mass density ϱ, λ (the Lamé constant), and μ (the shear modulus).

Regarding the relationship $\Delta v/v = -\Delta f/f$ between SAW velocity and the variation in the SAW dual-delay line oscillator frequency, perturbation analysis leads to the following result for the relative frequency shift [249]:

$$\Delta f = (k_1 + k_2)\, f_0^2 t_f\, \varrho - k_2 f_0^2 t_f \left[\frac{4\mu\,(\lambda+\mu)}{v_r^2\,(\lambda+2\mu)}\right] \quad (28)$$

where k_1 and k_2 are material constants for the SAW substrate. Additional information with respect to these equations is available from [224], [246], [249].

Thus, the film mass per unit area is $t_f\,\varrho$. If chemical interaction does not alter the mechanical properties of the film, the second term in Equation (28) can be neglected, in which case the frequency shift Δf can be attributed exclusively to the added mass:

$$\Delta f = (k_1 + k_2)\, f_0^2 t_f \varrho \quad (29)$$

Coating a polymer film 1 µm thick onto a quartz SAW sensor operating at 31 MHz should therefore cause a frequency shift $\Delta f = -130$ kHz [231].

Figure 49. Lamb waves propagating in a thin plate-mode oscillator (PMO) [226], [231] (with permission from Plenum Publishing, New York)
A) Symmetric waves; B) Antisymmetric waves

Plate-Mode Oscillators (PMOs). *Lamb Wave Oscillators.* In all the SAW devices discussed above, the acoustic wave propagates in a slab of material whose thickness is infinitely larger than the wavelength λ of the propagating wave. When the thickness of the plate is reduced to such an extent that it becomes comparable to λ, the entire plate becomes involved in the periodic motion, producing a symmetric and antisymmetric *Lamb wave* (LW) (Fig. 49). This behavior is observed in plate-mode oscillators with thicknesses of a few micrometers. A cross-sectional view through a typical PMO is shown in Figure 50.

Figure 50. Cross section through a Lamb wave PMO, including the corresponding interdigital transducers [228]

Certain performance factors make the LW-PMO potentially attractive as a chemical sensor. Both surfaces contribute to the signal, so the observed sensitivity is greater than for a corresponding SAW device. However, the most important advantage follows from the fact that the velocity of the lowest-order wave in the antisymmetric mode is much lower than in the case of the corresponding SAW oscillator. This may be important for applications involving mass-sensing in liquids, which are problematic with high-frequency SAW devices. As the frequency of the Lamb wave decreases below the velocity of the compressional wave in the liquid, energy loss in the perpendicular direction decreases as well. A Lamb wave also has a greater frequency dispersion than the corresponding surface acoustic wave, resulting in increased resolution and sensitivity.

However, there are certain practical problems. The fragility of the thin plate and its consequent sensitivity to external pressure is particularly serious. Performance analyses as well as details regarding fabrication of the device can be found in the original paper [227].

Acoustic Plate-Mode Oscillators and Love Plate Devices [254]. These two types of acoustic PMOs, like BAW sensors, are characterized by surface-guided, shear-horizontally (SH) polarized waves, which have a horizontally polarized component of displacement (see also Fig. 58). In principle the performance of such APMs is similar to that of the Lamb wave sensors described above, but the thickness of the substrate

is greater, so waves propagate from the surface into the bulk of the material. Energy is confined mainly in the bulk of the plate as the wave propagates through multiple reflections, generating displacements in both the upper and lower surfaces. The Love plate sensor includes a waveguide structure, whereby the SH wave is confined within an elastic layer deposited on a SAW substrate capable of supporting SH waves. Figure 51 provides cross-sectional views of APM and Love plate devices.

Figure 51. Cross-sectional view of (A) APM and (B) Love plate devices [254]

Acoustic sensors based on SH waves have become rather widespread due to their ability to function in liquid media.

Relative Sensitivities of BAW, SAW, LW, APM, and Love Plate Devices. Because of excitation and propagation differences among the various transducers described, the mass-deposition sensitivity of the several devices would be expected to vary considerably, with some geometries proving more attractive than others for particular sensing applications. Table 10 offers a performance comparison for these transducers. Table 10 also summarizes the calculated frequency-to-mass sensitivities for the various devices. Sensitivity variations can be explained on the basis of energy confinement on the sensing surface and a particular device's operating frequency. A decrease in the thickness of the substrate leads to a sensitivity increase, which can be realized with either an acoustic plate-mode or a Lamb wave device. These are therefore associated with the highest sensitivities, followed by the Love plate, which also has a very thin layer. Less sensitivity is available with BAW devices, for which the sensitivity depends on the thickness of the crystal.

The above statements have to be corrected because of very recent developments. With the commercial availability of a 155 MHz BAW quartz at reasonable prices the QMB should be more favored. According to the Sauerbrey equation the new BAW device shows a much higher sensitivity than the traditional 10 MHz QMB. Table 11 summarized recent data of the different noise levels published in the literature. By this it becomes evident that the new 155 MHz device will be the transducer of choice when an extremely sensitive gas sensor transducer is needed. This sensor also shows almost no drift. Thus drift compensation methods often used with SAW devices are no longer needed. The price of only a few Euro for this mass-produced unit will make it highly competitive in sensor applications.

2.3.3.3. Theoretical Background

Piezoelectricity. *The Piezoelectric Effect.* Because all acoustic gravimetric sensors are based on the phenomenon of piezoelectricity, it seems appropriate to discuss briefly the effect itself. Piezoelectricity was first observed by the Curie brothers (Jaques and Pierre) in 1880 [258]. It is a reversible phenomenon, consisting of linear electromechanical interactions between mechanical and electrical properties in certain crystals (Fig. 52). The effect is generated, as already mentioned, by application of an AC potential to the piezoelectric material via contact electrodes. One can distinguish between bulk- and surface-generated AW (BAW and SAW, respectively) when the electric field is applied across the substrate or only at its surface, respectively.

A piezoelectric effect occurs only with those ionic crystalline solids whose crystals contain a polar axis along which the physical properties are not constant. The *direct* piezoelectric effect is observed when an applied force (F) produces an electrical polarization (P), and a *converse* (reciprocal) piezoelectric effect results when an applied electrical field (E) induces a strain (S, deformation of the crystal) (Fig. 53).

A simplified view of piezoelectricity at the microscopic level is provided by the example of α-quartz (Fig. 54). Here a net dipole mo-

ment will arise if the hexagonal structure is stretched or compressed along a direction parallel (Fig. 54 B) or perpendicular (Fig. 54 C) to one of the three in-plane symmetry axes. When symmetry is achieved, the net dipole moment of the molecule vanishes.

Structural Aspects of Piezoelectric Solids. In order for a crystal to be piezoelectric it must be noncentrosymmetric; i.e., it cannot contain a center of symmetry. Solids are usually grouped for structural characterization purposes into seven crystal systems (from lowest to highest symmetry: triclinic, monoclinic, orthorhombic, tetragonal, trigonal, hexagonal, and cubic), which can in turn be divided into 32 point groups, depending upon point symmetry. Of these, 11 classes are centrosymmetric and 20 are piezoelectric. An exceptional case is class

432 from the cubic crystal system, because it is neither centrosymmetric nor piezoelectric. In addition to the 21 noncentrosymmetric classes, 11 classes can be distinguished on the basis that they possess no plane of symmetry. This means that they are associated with both right- and left-handed forms, which cannot be interconverted by simple rotation, a phenomenon known as enantiomorphism [261].

Figure 53. Schematic representation of the direct piezoelectric effect (A) and the converse (reciprocal) piezoelectric effect (B) for an X-quartz plate (right-handed quartz) [222]
F = Applied force; P = Polarization; E = Applied electrical field
(with permission from Springer-Verlag, Heidelberg)

Table 12 summarizes on the basis of international point-group symbols the structural distribution with respect to piezoelectric classes, centrosymmetric classes, and enantiomorphism. For example, $LiNbO_3$, which belongs to the class $3\,m$, is piezoelectric, but not enantiomorphic, whereas α-quartz, in class 32, is both piezoelectric and enantiomorphic. The latter characteristic is illustrated in Figure 55.

Not every solid material associated with a piezoelectric class is suitable for practical applications, because in some cases the piezoeffect is too weak. Large piezoelectric coefficients are a prerequisite for an electromechanical transducer, like those found, for example, with α-quartz or $LiNbO_3$. Therefore, these are the solids most often used as mass-sensitive plates or substrates.

Table 12. Distribution of crystal structures (point groups) with respect to centrosymmetric, piezoelectric, and enantiomorphic classes [261]

Crystal system	Centro-symmetric classes	Piezoelectric classes	Classes with enantiomor-phism
Triclinic	$\bar{1}$	1	1
Monoclinic	$2/m$	$2, m$	2
Orthorhombic	mmm	$222, mm2$	222
Tetragonal	$4/m, 4/mmm$	$4, \bar{4}, 422, 4mm, 42m$	4, 422
Trigonal	$\bar{3}, \bar{3}m$	$3, 32, 3m$	3, 32
Hexagonal	$6/m, 6/mmm$	$6, \bar{6}, 622, 6mm, 6m2$	6, 622
Cubic	$m3, m3m$	$23, \bar{4}3m$	23, 432

Theory and Physics of Piezoelectricity. The discussion that follows constitutes a very brief introduction to the theoretical formulation of the physical properties of crystals. If a solid is piezoelectric (and therefore also anisotropic), acoustic

Figure 54. Physical interpretation of the piezoelectric effect [260]

displacement and strain will result in electrical polarization of the solid material along certain of its dimensions. The nature and extent of the changes are related to the relationships between the electric field ($\boldsymbol{E}$) and electric polarization ($\boldsymbol{P}$), which are treated as vectors, and such elastic factors as stress $\boldsymbol{T}$and strain ($\boldsymbol{S}$), which are treated as tensors. In piezoelectric crystals an applied stress produces an electric polarization. Assuming the dependence is linear, the direct piezoelectric effect can be described by the equation:

$$\boldsymbol{P}_{\mathrm{i}}=d_{\mathrm{ijk}}\boldsymbol{T}_{\mathrm{jk}} \text{ or } \boldsymbol{P}_{\mathrm{i}}=e_{\mathrm{ijk}}\boldsymbol{S}_{\mathrm{jk}} \tag{30}$$

The quantities d_{ijk} and e_{ijk} are known as the *piezoelectric strain* and *piezoelectric stress* coefficients, respectively.

Figure 55. Major crystal surfaces of α-quartz together with their Bravais – Miller indices (hk.l) (with permission from The Institute of Electrical and Electronics Engineers, New York)
A) Left-handed form; B) Right-handed form; Cartesian coordinates are specified in accordance with the IEEE standard of 1987 [229]

Conversely, if such a crystal is placed in an electrical field it will become deformed, a phenomenon known as the converse or reciprocal piezoelectric effect (Fig. 53 B). The contributions of stress and strain in this case can be expressed:

$$\boldsymbol{S}_{\mathrm{jk}}=d_{\mathrm{ijk}}\boldsymbol{E}_{\mathrm{i}} \text{ or } \boldsymbol{T}_{\mathrm{ij}}=e_{\mathrm{ijk}}\boldsymbol{E}_{\mathrm{i}} \tag{31}$$

Since the stress and strain tensors are symmetric, the piezoelectric coefficients can be converted from tensor to matrix notation. Table 13 provides the piezoelectric matrices for α-quartz together with several values d_{ijk} and e_{ijk}, including the corresponding temperature coefficients [259], [261].

Figure 56. Oriented quartz crystal cuts in relation to the natural crystal [209] (with permission from Elsevier, Amsterdam)

For sensor applications, the magnitudes of d_{ijk} and e_{ijk} should be as great as possible, and the temperature dependence should be as small as possible. Although lithium niobate displays larger stress and strain constants than α-quartz, the temperature influence in this case is also great. Therefore, α-quartz is the material most often selected for piezoelectric sensor applications. Because of the anisotropic behavior of a piezoelectric material, properties like resonance frequency and temperature dependence can be optimized by cutting a plate from a single crystal in a particular way. Figure 56 shows two possible cuts with respect to a natural α-quartz crystal. For use as acoustic gravimetric sensors, only AT- and BT- cut quartz plates are useful. These *y*-rotated cuts provide two different high-frequency plates that vibrate in a shear mode along an axis parallel to the major surface, as indicated previously (see also Fig. 43 B). Minimizing temperature effects requires that the plate be cut at a very precise orientation. The temperature dependence of the relative frequency for various cuts of quartz crystal is shown as a function of the angle of cut in Figure 57 [262].

More detailed theoretical treatments of piezoelectric solids and their properties are provided by [222], [263–265]. Another more sophisticated approach based on dynamic quantum mechanics is presented in [266]. Interest has also developed in piezoelectric polymers, especially

as a result of their strongly piezoelectric properties [222].

Figure 57. Temperature dependence of the relative vibrational frequency for different AT-cuts of a quartz crystal [262] (with permission from Elsevier, Amsterdam)

Vibrations and Waves. The theory of acoustic waves in solids is well understood, and many comprehensive descriptions exist [249], [267]. The description presented here should suffice to explain sensor function despite the fact that it is limited and qualitative.

Acoustic waves in solids consist of oscillatory motions of the material comprising the solid. The stress – strain relationship treated in the preceding section leads ultimately to two types of acoustic displacements: *longitudinal* or *tensile* motions that cause the dimensions of the solid body to change along a single direction without accompanying changes along the orthogonal directions, and *shear* motion, which produces changes in the shape of the solid body. Figure 58 illustrates these two types of motion [256].

In piezoelectric solids, an applied force generally creates both quasi-longitudinal and quasi-shear waves, where the acoustic displacement in a wave will be largely either longitudinal or shear. Pure longitudinal (L) and shear waves (SH = horizontally polarized shear waves; SV = vertically polarized shear waves) are generated if wave propagation occurs along certain crystallographic axes or with specific orientations. The generation of mixed wave types is also possible, but normally not desirable for sensor applications.

Figure 58. A) Schematic representation of longitudinal and shear displacement [256]; (with permission from Elsevier, Amsterdam) B) Grid diagrams for plane uniform waves propagating along the z axis in a material of infinite extent [248] (with permission from J. Wiley & Sons, New York): (1) Tensile motion (one dimension); (2) Shear motion (two-dimensional; y-polarized in this case)
L = Longitudinal (tensile) motion; SH = x-Polarized shear (horizontal); SV = y-Polarized shear (vertical)

As far as microgravimetric sensors are concerned, two types of wave-propagation devices can be distinguished: those characterized by wave propagation perpendicular to the plate surface (BAW) and those in which the waves propagate along the surface (SAW) or in the bulk of the substrate (LW, APM). Transducers of the former type are normally resonators. A given device might be designed to utilize either longitudinal or shear waves propagated between the faces, as in microbalances based on AT- or BT- cut quartz plates operating in their SH high-frequency fundamental mode. Only acoustic waves satisfying boundary conditions for the resonator surfaces will propagate efficiently across such a device. The waves can be visualized as standing sinusoidal waves with displacement nodes at the resonator surfaces (see 2.3.3.2).

Transducers in the second category include wave delay-line oscillators (see Figs. 42 and 47), which are based primarily on two types of waves. One is a coupled linear combination of two wave-equation solutions, an L-wave and an SV-wave. In this wave, also called a Rayleigh wave, particle displacement takes the form of an elliptical motion in the plane perpendicular to the surface (sagittal plane) and containing the direction of propagation. Some displacement also occurs outside the sagittal plane, but the deviations are minor (Fig. 59). Two of the most important cuts providing these wave types, and which are used in chemical sensors, have been illustrated in Figure 56. Waveguides that rely on Rayleigh wave devices for their operation are often referred to as surface acoustic wave (SAW) devices, and they have been extensively employed as sensors.

The second type of wave in this context is a horizontal shear (SH) wave, whose acoustic displacement is in the plane of the waveguide. An SH wave generally travels at a different velocity than a Rayleigh wave, and for piezoelectric waveguides the SH wave becomes a true surface wave provided the acoustic impedance at the surface differs from that in the substrate bulk. Such a difference can be caused by piezoelectric stiffening of the SH mode, deposition of a layer of dissimilar material on the surface, the presence of a surface grating, or liquid in contact with the surface. Depending on their origin, SH surface waves are referred to in the literature as Bleustein – Gulayev (BG) waves, Stoneley waves, SH-SAW, or surface transverse waves. Pure surface transverse waves (shear waves) appear to show promise for applications in liquids, especially biosensor applications, because the dissipation of energy across the phase bound-

Cut	Designation	Type of wave	Operating frequency
AT-Quartz	(YXl)-35°	Thickness shear mode	0.5-100 MHz

Figure 59. Wave properties associated with several different types of quartz cuts [260]; see also Figure 48

ary into the liquid is approximately zero, which greatly reduces the generation of longitudinal sound waves in the liquid itself.

Plate-mode waves are analogous in form to Rayleigh and SH waves in a semi-infinite waveguide. Two groups of plate modes can be distinguished: the first consists of Lamb waves or flexural waves, where the acoustic displacement is a combination of longitudinal and vertical shear motion; a second family involves SH acoustic displacement [256]. Because of their frequency range (100 kHz to the GHz region) these sound waves fall in the ultrasound category, with a propagation velocity of 1 – 10 km/s (cf. electrical signals, which travel at 100 000 – 300 000 km/s).

Interdigitated Transducer (IDT). The IDT was invented by White and Voltmer in 1965. The IDT is a planar, interleaved metal structure at the surface of a highly polished piezoelectric substrate (see Figure 60). The adjacent electrodes are given equal potentials of the opposite sign. The resulting spatially periodic electric field produces a corresponding periodic mechanical strain pattern employing the piezoelectric effect. This gives rise to generation of surface acoustic waves (SAW), provided that the surface is stress free. In general both SAW and BAW may be generated by IDT.

Figure 60. Layout of an Interdigitated Transducer (IDT) with period a and aperture A. The period determines the wavelength of the generated SAW $\lambda = a$. The aperture determines the width of the radiated beam and is typically 10 – 100 wavelengths in magnitude. The IDT length is $L = N\lambda$, when IDT contains N electrode pairs

The IDT behaves as a sequence of ultrasonic sources. For an applied sinusoidal voltage, all vibrations interfere constructively only if the distance $a/2$ between two adjacent fingers is equal to half the elastic wavelength. The frequency $F_0 = V_{AW}/\lambda = V_{AW}/a$ that corresponds to this cumulative effect is called the synchronous frequency or the resonance frequency. The bandwidth of an IDT is narrower, when there are more fingers. When IDT is used the AW velocity is determined by the plate material and orientation, while wavelength depends only on the ITD periodicity.

SAW are emitted in both opposite directions, which result in an inherent minimum of 3 dB transducer conversion loss at F_0. A minimum insertion loss of 6 dB is found for a delay line. The acoustic aperture A defines the effective region of transduction between two adjacent electrodes. The IDT is uniform if a constant aperture is obtained.

SAW component design is based on the application of an equivalent circuit model [29] using the values of the piezoelectric coupling coefficient of the material, F_0, and the static capacitance [30].

The frequency at which the AW device operates depends on:

- the acoustic wave velocity in the substrate material
- the IDT finger spacing (for SAW)
- the substrate (plate) thickness

Additionally, the type of AW generated by IDT depends on:

- the crystal cut
- the orientation of the IDT relative to the crystal cut
- the substrate (plate) thickness
- the wave guiding mechanism (BAW, SAW, APM)

Acoustic wave devices (AWD). Figure 61 shows an overview of the basic types of AWDs, indicating the polarization of the generated acoustic waves, and whether the devices can be operated in liquid.

2.3.3.4. Technical Considerations

The (Bio)Chemical Interface. A piezoelectric transducer is transformed into a mass-sensitive sensor by coating it with an appropriate (bio)chemical film or layer, which may

Figure 61. Flow diagram illustrating the basic types of acoustic wave devices. Here, *d* is the substrate (vibrating plate) thickness and l is the acoustic wave wavelength

be inorganic, organic, or even metallic in nature. Ideally the film should be strongly adherant and deposited in such a way as to obtain a plane surface. Concerning immobilized large biomolecules, certain doubts exist over the demand for a plane surface and the request for a strong adherence. It seems highly unlikely that an immobilized macromolecule will follow any surface movement of the transducer as a whole entity given its flexible structure. The thickness of such a layer is usually on the order of 1 – 100 µm depending upon the nature of the transducer. The chemically sensitive layer serves as an interface between the environment and a data-processing system, and it is responsible for both the sensitivity and the selectivity of the sensor. This layer should display the following properties:

1) Reversibility, sensitivity, and selectivity
2) Inertness with respect to chemical cross-influences, such as humidity or carbon dioxide
3) Ease of coating, strong adhesion, and long life

Most chemically sensitive layers are insulators, such as organic substances with special functionalities, but conducting materials such as metal films or conducting polymers are also useful. Examples include:

1) Donor – acceptor functionalities; e.g., carbocations [268], M(II)porphyrins [269], or betaines [270]
2) Host – guest binding systems (supramolecular compounds); e.g., molecular cavities [271], clathrate systems [272]
3) Pure metallic layers; e.g., palladium for the detection of hydrogen [273]

Interaction of the Chemical Layer with an Analyte. Interaction with an analyte can take many forms ranging from adsorption – absorption to chemisorption, including the compromise of coordination chemistry. The following types of chemical interactions can be distinguished [274]:

1) *Absorption.* Here the analyte is distributed between the chemical interface (a liquid film, amorphous solid, or polymer, analogous to the stationary phase in gas chromatography) and the surrounding medium. In the case of a gas interacting with the chemical interfacial layer, once equilibrium has been achieved the amount of analyte present in the layer is a function of the partition coefficient between the gas and the interface (as specified by Raoult's and Henry's laws) as well as the thickness and area of the interface. Because distribution tends to be determined mainly by the polarity of the chemical interface and the analyte, little selectivity is expected.
2) *Adsorption.* The analyte in this case interacts only at the surface of the interfacial layer, and no chemical bonds are formed or broken. Attraction energies are usually in the range 0 – 10 kJ/mol (i.e., attributable to van der Waals forces), extending in the case of hydrogen bonds to as much as 40 kJ/mol. Adsorption may result from physical attraction between a nonreactive gaseous analyte and a metal surface, for example, or formation of a donor – acceptor association (H^+ or e^-). Adsorption is a universal phenomenon, and it is quite nonselective. The basic principles of gas adsorption have been described by Langmuir [275] and de Boer [276].
3) *Chemisorption* [277]. Chemisorption involves very strong interaction – up to ca. 300 kJ/mol – developed at the surface of the chemical interface, including the formation and breaking of chemical bonds. High selectivities can therefore be anticipated, but there is a simultaneous loss of reversibility. Because of the partially irreversible nature of bond formation, such a sensor would actually behave more like a dosimeter, although this might be advantageous in some applications.
4) *Coordination chemistry* [274]. A compromise offering both selectivity and reversibility of analyte binding is presented by the area of coordination chemistry. A typical coordination compound consists of a central metal ion M surrounded by a neutral or charged (often organic) ligand. The extent of selectivity can often be influenced by the choice of the metal ion as well as by the choice of the ligand – taking into account both electronic and steric factors. Complexation with an analyte produces changes in the properties of the coordination compound, and these changes can be subject to detection. The selectivity is a function of structural, topological, and polarity parameters.

Other types of chemical interfaces have also been used for microgravimetric gas detection, including polymeric phthalocyanines [278], porphyrins [279], ferrocenes [280], metal clusters [281], crown ethers [282], and cyclodextrins [283].

In many cases it has proven to be very difficult to find a selective chemical interface for a particular analyte, so the use of sensor arrays has been proposed. Numerous papers have dealt with this approach, invoking both BAW and SAW sensors. Pattern-recognition techniques employing increasingly powerful microprocessors are required to generate the appropriate signals [284].

Coating Methods. The stability of a (bio)chemical interface depends heavily on the attachment of the material to the surface of the sensor device. One or more of the following coating methods is employed according to the nature of the sensitive layer:

Smearing [224]
Spin coating [285]
Drop coating [103], [257]
Solvent evaporation [286]
Spraying [287]
Langmuir – Blodgett film formation [288]
Physical vapor deposition [289]
Sputtering [290]
Chemical immobilization [291]

The first five methods listed involve simple coating procedures in which the interfacial material (usually nonpolar) is dissolved in an organic solvent and then deposited directly onto the substrate surface. Evaporation of the solvent leaves a film that adheres to the surface of the substrate by physical bonds. The

Langmuir – Blodgett technique makes it possible to achieve very thin films. This is a dipping procedure in which molecules are transferred with great accuracy from the surface of a liquid to the surface of the substrate. Even monolayers can be prepared in this way. More complicated methods include physical vapor deposition (PVD) and chemical vapor deposition (CVD). Very planar layers can be achieved in this way, but the reaction conditions are usually quite drastic, so the technique is essentially restricted to materials that are relatively inert, such as inorganic compounds or metals.

2.3.3.5. Specific Applications

Having reviewed the fundamental aspects of microgravimetric transducers and piezoelectric solids with respect to the generation and propagation of vibrations and waves, it is now appropriate to turn to the practical considerations of instrumentation and application, addressing first the BAW devices.

Figure 62. Typical experimental apparatus based on a piezoelectric quartz-crystal detector [217] (with permission from Elsevier, Amsterdam)

Bulk Acoustic Wave Sensors. *Experimental Arrangement.* A typical experimental setup involving a piezoelectric mass-sensitive quartz crystal detector is depicted schematically in Figure 62 [217]. The piezoelectric quartz crystal (a) is shown here inserted directly in a gas stream (b) with a flow velocity of ca. 10 – 100 mL/min, but a measuring cell containing a stationary atmosphere of the analyte gas is also useful. The oscillator (e) is usually powered by a regulated power supply (d; e.g., 5 – 15 V) that drives the quartz crystal. The frequency output from the oscillator is monitored with a frequency counter (f), which should be modified by a digital-to-analog converter (g) to permit the frequency data to be recorded.

Parameters that adversely affect the performance of a piezoelectric sensor include the mass of the chemical layer, built-in stress produced by the chemical layer, stress from the electrodes (clamping), and changes in temperature. A more sophisticated device such as a microprocessor-controlled dual- crystal instrument would be required to eliminate these undesirable effects [292].

The device described is designed for measurements in the gas phase; applications in a liquid medium demand an extended version, including a liquid-tight box, an oscilloscope or network analyzer, and provisions for more detailed signal analysis (impedance analysis). Improvements in the oscillating circuit are particularly important for obtaining satisfactory results with liquids [293–295]. A proper interpretation of any observed frequency change in liquid media still remains. Can the densitiy and the viscosity of the sample liquids be controlled so accurately (sometimes within the fifth digit after the decimal point) and does the surface roughness not change during the measurements increasing the viscoelastic effects?

Applications. This section will be limited to a brief consideration of the use of BAW sensors in gas-sensing devices and as sensors for liquid phases. Piezoelectric microbalances can also be used for monitoring such heterogeneous samples as aerosols and suspensions, as discussed in [262].

Gas-Phase Sensing. In principle, both inorganic and organic analytes are subject to detection. Figure 63 provides an example of results obtained from the novel 155 MHz piezoelectric quartz microbalance (QMB) resonator used to detect gaseous tetrachloroethylene (C_2Cl_4). The used absorption layer was polyepichlorhydrin (PECH). Observed response curves are illustrated as a function of time and for various analyte concentrations. [257].

A wide variety of solvent vapors can be detected with this new QMB with extremely high sensitivity (starting in the ppb range) and showing a dynamic working range of up to 4 decades

Figure 63. QMB-based gas sensing with polyepichlorohydrin (PECH) as polymer. The upper original recorder traces show 13 complete calibration cycles and demonstrates the very high reproducibility of this gas sensor in this low concentration range. The lower part shows the details of one cycle between 2.5 and 20 ppm tetrachloroethene. With a sensitivity of ≅ 10 Hz/ppm tetrachloroethene and an LOD of about 100 ppb this device is more sensitive than any Taguchi gas sensor or the FID considering its low noise, in the range of only about 0.5 Hz! Compared with a 25 MHz QMW the sensitivity could be increased by one order of magnitude [257]

with response times below 10 s, indicating the potential of this approach to gas-phase monitors and sensors for applications in environmental analysis or process control.

Table 14 provides an overview of the detection of selected gaseous analytes. Information regarding interfering gases can be found in the original literature. The effect of changes in the relative humidity of the environment tends to be a general problem.

Applications in Liquids. Apart from the classical sensors designed for detecting ions, piezoelectric crystal resonators are the preferred devices for conducting biochemical measurements in liquids. Figure 64 illustrates results for the detection of human immunodeficiency virus (HIV) antibodies by means of a synthetic HIV peptide (p 24) immobilized on a piezoelectric quartz sensor. The data refer to the frequency shift observed upon addition of authentic HIV antibody. The quartz device was operated in this case in its fun-damental thickness shear mode at 20 MHz, with an oscillator circuit stability of ca. 0.5 Hz. The quartz plate was coated with HIV peptide (p 24) dissolved in phosphate buffer at a dilution of 1 : 1000. Figure 65 shows the corresponding response as a function of different concentrations of monoclonal HIV antibodies. This device has not yet been brought onto the market despite complete automation and further improvements. Thus, some remarks concerning mass-sensitive transducers employed in liquids must be made, since it is still doubtful if the frequency change observed by passing a sample solution over such a sensor surface really reflects a mass change. Even if the user will manages to control the density and viscosity of the sample solutions within a narrow range determined by the required sensitivity (up to 5 digits after the point) a change in the surface roughness by non-homogeneously attached macromolecules during the immuno reaction may affect the vis-

Surface Acoustic Wave Sensors. Many reports have appeared regarding the use of SAWs as gas detectors. These reports also discuss problems associated with the choice of a coating, achieving adequate specificity, selecting a coating thickness, and depositing reproducible levels of polymer coating on the surface of the sensing element. The variety of coatings used is as diverse as the nature of the analytes, covering the range from simple polymers through metallocyanines to metal films [308]. The main drawback after the introduction of the 155 MHz QMB was the lack of availability and the price. Concerning the LOD, their inherent higher noise excludes, in general, the ppb range. The application of SAW sensors in liquid systems is still an active area of research, so this topic will not be treated. Information regarding liquid applications for mass-sensitive devices, especially SAW, APM, and LW devices, is provided in [309], [310].

Experimental Arrangement. A schematic representation of a SAW sensing device is provided in Figure 66. This particular resonator was used by D'Amico et al. [311] for the detection of

hydrogen. It consists of a dual delay-line structure in which one of the propagation paths (l_S) is coated with a thin palladium film to act as the sensing channel, while the other (l_R) is uncoated and serves as a reference.

Figure 66. Schematic representation of a SAW hydrogen sensor [311] (with permission from Elsevier, Amsterdam) a) Palladium film; b) Acoustic absorbers; c) YZ-$LiNbO_3$; d) "Stretched line," an adjustable resistance for matching the frequency of V_R to that of V_S; e) Input transducer T; f) Output transducer T_R; g) Output transducer T_S; l_R, l_S = Propagation path (l_R is the distance between T_R and T; l_S between T_S and T); L_T, L_R, L_S = Series inductors (establishing a fixed e.g., 50 Ω electric input – output impedance); V_R, V_S = Output voltage of the dual delay line

Applications. The type of results to be expected with a variety of analytes in the gas phase is illustrated by the example of an NO_2-SAW sensor. The device in question was developed by Nieuwenhuizen and Venema [312], and had an operating frequency of 79 MHz with a metal-free phthalocyanine coating. A frequency change of ca. 670 Hz was observed upon exposure of the sensor to 88 ppm of nitrogen dioxide in air at 150 °C. Figure 67 A demonstrates the sensitivity of the device as a function of nitrogen dioxide concentration, while Figure 67 B shows the response of a typical sensor as a function of time with alternating exposure to nitrogen dioxide and air. Possible interferences were also investigated, as described in a similar report published earlier by the same authors [313].

A summary of selected papers describing the use of SAWs for gas sensing is provided in Table 15, subdivided according to the type of analyte.

Figure 67. A) Sensitivity of an NO_2-SAW resonator at 120 °C (●, ■, △) and 150 °C (○, □, ▲) with three different metal-free pthalocyanine layers: PC 42 (●, ○), PC 46 (■, □) and PC 47 (△, ▲) [312]; B) Sensor output as a function of time at 150 °C (PC 42, 88 ppm of NO_2)

2.3.3.6. Conclusions and Outlook

Mass-sensitive devices offer great promise as chemical sensors, particularly since they rely on the most basic physical effect that accompanies the interaction of one chemical substance with another: the mass effect.

Both BAWs and SAWs have already been successfully applied to the monitoring of many gases, vapors, and more recently, liquids. One of the most critical aspects of chemical sensor research is the search for a suitable chemical interface. The selectivity and sensitivity of mass-sensitive devices can be improved by the use of more carefully designed polymers and other special coating materials. Correction algorithms might also be developed to compensate for variations due to changes in humidity, temperature,

pressure, etc. Humidity poses one of the greatest problems with respect to most sensing devices. Better design of the electronic oscillator circuits might also increase the stability of the signal in response to a gas or vapor, thereby improving the signal-to-noise ratio and raising the level of sensitivity.

Research on chemical sensors tends to be unusually multidisciplinary. Such new techniques as the use of Love plates and LW-APM make it possible to combine the advantages of microcompatibility, high sensitivity, and suitability for work in both the gas and liquid phases. In particular, the new 155 MHz BAW could open up new horizons in gas sensor developments and electronic noses. The higher sensitivity of this transducer now allows dynamic ranges larger than 4 orders of magnitude with response ranges in the seconds range. Taking the first derivative of the absorption or desorption signal this device can be used as a more or less selective GC detector [257]. A 5 ppm peak of tetrachlorethene can then be sensed with a signal-to-noise ratio of about 3000.

Nevertheless, anyone proposing to conduct investigations in this area should be aware of the complexity of interpreting data accumulated from multicomponent gas mixtures over a prolonged period of time, and of parameter identification and interpretation in the case of liquids [230], [308].

2.3.4. Calorimetric Devices

Introduction. Most chemical as well as enzyme-catalyzed reactions are accompanied by changes in enthalpy. For this reason, calorimetric transducers represent a universally applicable approach to chemical or biochemical sensors.

Thermal devices for detecting an enthalpimetric effect (either exo- or endothermic) are insensitive to changes in optical properties of the sample, so colored solutions and turbidity do not constitute interferences. There is also no need for a detectable reaction product, whereas amperometric sensors, for example, require the formation of some product subject to transformation at an electrode. Amplification can be achieved by immobilization of a catalyzing reagent that enhances the rate of enthalpy change. Thermal transducers are especially suitable for continuous measurements in flow systems. An important disadvantage, however, is the requirement for thermostatic control of the device. For this reason calorimetric systems tend to be rather large. In addition, calorimetric sensors are relatively complicated to use [326], [327]. Table 16 provides molar enthalpies for several important types of chemical reactions.

The measurement signal in this case, ΔT, is related to the change in enthalpy ΔH, but also to the heat capacity of the system c_s, according to the following equation:

$$\Delta T = n\Delta H / c_s$$
$$n = \text{Moles of product} \tag{37}$$

This means that the heat capacity of the sensor itself should be minimized to ensure sensitive measurements. A temperature change can easily be transduced into an electrical signal. The usual measuring device is based on a reference

thermal transducer incorporated into a Wheatstone bridge.

Table 16. Molar reaction enthalpies for selected processes [328], [329]

Reaction	Examples	Enthalpy $-\Delta H_R$, kJ/mol

	enzyme: glucose oxidase; substrate: glucose	80

Thermal Transducers Commonly Utilized in Chemical and Biochemical Sensors. *Metal-Resistance Thermometers.* The electrical resistance of many metals rises sharply with increasing temperature. Resistors made of platinum (called "Pt 100" because they provide a resistance of 100 Ω at 0 °C) are often used for temperature measurement in the range from − 220 °C to +750 °C. Other metals like nickel or copper are also applicable for temperatures ≤ 150 °C. Self-heating, caused by a current flow, interferes with the measurement, and the response time of a metal resistor is relatively long (ca. 5 s). The advantages of such resistors are high sensitivity and long-term stability. Platinum resistance devices are especially common in catalytic chemical sensors. A reducing gas may be oxidized in the presence of a heated catalyst (e.g., Rh, Pd, or Pt) in order to increase the reaction rate. In 1962 Baker [330] described a device called a *pellistor* that effectively separates the catalyst from the platinum wire (see Fig. 68). The detection limit for methane with this device was found to be 20 ppm.

Thermistors. These are semiconductor resistances with temperature coefficients sufficiently high to make them suitable for use in temperature measurement. Many semiconductors have negative temperature coefficients (NTC), which means that their resistance decreases with increasing temperature. Thermistors with reproducible temperature coefficients are difficult to produce, and self-heating within the sensor is always a problem. On the other hand, thermistors are usually both inexpensive and sensitive, and they can be used over a wide temperature range (0 – 1000 °C).

Figure 68. Pellistor device
a) Metal resistor; b) Inactive material; c) Catalyst

The thermistor most commonly used in chemical or biochemical sensors, known as an *enzyme thermistor* (ET), was designed in 1974 by Mosbach et al. [331]; it consists of an enzyme reactor specially adapted for use in a flow system. A split-flow arrangement was suggested in 1976 [332], whereby one portion of the analyte solution serves as a reference and flows through a blank column, while another passes through the enzyme reactor itself. The reference signal is subtracted from the signal produced by the enzyme reactor (Fig. 69) [333]. Samples are analyzed at a rate of ca. 20/h. Since the enzyme reaction and the detecting system are separated in space, an enzyme sensor of this type cannot be strictly interpreted as a "biosensor" according to the definition provided in Section 3.

Many other devices featuring lower detection limits have been developed, including a four-channel enzyme-based thermistor that permits the detection of four substrates simultaneously [334]. Another approach involves fabrication of a thermal microbiosensor on a silicon chip. In this case the sensor consists of a micromachined enzyme reactor, inlet and outlet flow channels, and a microthermistor [335].

Thermocouples/Thermopiles. Thermocouples operate on the basis of the Seebeck effect. If wires fabricated from two different metals or

Figure 70. Construction details of a microsystem technology approach towards thermopiles. The extremely sensitive thermopile was produced in the "Institut für physikalische Hochtechnologie" IPHT - Jena

semiconductors are soldered together to form a circuit, any temperature difference that exists between the joined points leads to a measurable potential difference, the magnitude of which depends on the extent of the temperature difference and the materials involved. The use of several thermocouples connected in series (*thermopiles*) increases the sensitivity of the sensor, but if a single thermocouple is damaged the entire sensor is affected. It is more difficult to miniaturize thermoelectric sensors than resistance devices, and the long-term stability of thermocouples is often not good. A typical response time is less than one second, and sensors of this type can be used over a temperature range from $-200\,^{\circ}$C to $+1600\,^{\circ}$C.

Thermal devices based on thermocouples have been extensively investigated in recent years. Guilbeau et al. described in 1987 a thermoelectric sensor for the measurement of glucose [336]. This device incorporated an antimony – bismuth thin-film thermopile with enzyme immobilized on the side containing the active junctions but not on that of the reference junctions. Exposing the sensor to a solution containing the substrate causes the enzyme-catalyzed reaction to take place, resulting in heat exchange that is detected by the thermoelectric transducer. At the ICB Muenster, a thermopile produced with microsystem technology in the "Institut für physikalische Hochtechnologie" IPHT Jena (Germany) with the extreme sensitivity of about 10^{-4} K has been used for constructing a GOD-based glucose sensor which does not need any calibration. Figure 70 shows the construction of the thermopile with the microsystem technology.

Figure 71 shows the experimental set-up for absolute glucose sensing via the total heat of this specific GOD-based enzymatic reaction, which is strictly proportional to the number of moles reacting [337]. The heat measured in the diagram ΔH versus the glucose concentration follows the theoretical predictions. Thus, no calibration has to be performed, and no standard is needed!

Summary. Most chemical calorimetric sensors are based on the pellistor device, and are designed for monitoring gases; sensor systems of this type have been subjected to intensive investigation [338]. In general, however, sensor determination of the heat of a reaction is rare, primarily because of the availability of other, more sensitive transducers. On the other hand, thermometric biosensors are applicable to a wide range of analytes, including enzyme substrates, enzymes, vitamins, and antigens. Many applications have been reported in clinical analysis,

process and fermentation control, and environmental analysis [339]. Thermal biosensors are seldom used in industry because they are difficult to control and relatively expensive. Universal applicability and new techniques for fabricating microthermosensors suggest that these may find wider use in the future.

2.4. Problems Associated with Chemical Sensors

All nonbiochemical sensors suffer from a lack of that selectivity which would permit their wide application without detailed knowledge regarding the matrix composition of the samples under investigation. Application is therefore restricted to those areas in which the sample matrix is thoroughly understood and not subject to change. Compared to the selectivity problem, all other problems (e.g., stability, sensitivity, lifetime) are relatively unimportant, since they can be resolved by incorporating the sensor into some type of intelligent instrument capable of carrying out all necessary corrections, recalibrations, and performance tests. In some cases insufficient selectivity of a chemical sensor can be circumvented by integrating a selective chemical reaction into the instrumental design. In this way many interfering compounds are eliminated and/or the analyte of interest is selectively transformed into a species capable of being detected unambiguously. A simple approach to this end takes advantage of the flow-injection analysis (FIA) technique.

Figure 71. Measuring cell for absolute calorimetric GOD-based glucose determinations. The opening must be minimized because otherwise the water evaporates too fast and interferes with the measurement by its heat of evaporation. In order to accelerate the enzymatic reaction peroxidase was added simultaneously. As soon as the drop of blood was added the temperature – time course was recorded and integrated. The glucose concentration can then be directly calculated via the published value for ΔH for this reaction as Figure 72 demonstrates

Any chemometric method of error correction with respect to lack of selectivity must be

Figure 72. Several measurements with known glucose concentration are plotted on a diagram calculated from the "theoretical" ΔH values for this aliquot. Note the thermopile and the set-up was not optimized further. The only drawback is the fact that both enzymes are lost after each determination as they are part of the receptor buffer solution. This is also the case in traditional enzymatic analysis with photometric evaluation. Here, only a so-called spectral-line photometer can work without further calibration

checked very carefully, especially if it is to be applied to an open system with varying and/or unknown interfering compounds. In some cases a prior chemical separation and/or selection step is required.

Despite the superb selectivity or even specificity of biochemical sensors for recognizing particular analyte molecules, interfering compounds must be dealt with even here in real sample applications. The compounds in this case do not disturb the actual measurement of the analyte; instead they influence the recognition process. For this reason it is important to ensure the use of a stable and well-defined host molecule with an analyte-fitting geometry that is not subject to change. Anything that might alter the host would influence analyte recognition. Thus, any compound or measuring condition capable of changing the tertiary structure of the sensitive protein skeleton of some biomolecule used for recognition purposes would disturb the measurement: first by modifying the selectivity, but also by altering the sensitivity. It is well established that most selective biomolecules are very stable only in a physiological environment similar to the one in which they were produced; even changes in the ionic strength can influence the tertiary structure of a delicate protein macromolecule. Furthermore, certain metal ions (e.g., Hg^{2+}, Pb^{2+}, Ag^{+}, Cu^{2+}) are known to be bound to sulfur containing molecules (or destroy a stabilizing S – S bridge in a protein) and thus degrade recognition and thus strongly interfere. A similar effect is produced by surface-active molecules (detergents). Bearing these complications in mind, the superb selectivity of biochemical sensors must be evaluated in a broader perspective.

2.5. Multisensor Arrays, Electronic Noses, and Tongues

Theoretically, and under ideal conditions, a sensor array containing several sensors with slightly different selectivities and sensitivities towards the analyte and its main interferences should make it possible to compensate for errors caused by the limited selectivity of each individual sensor. The task resembles the solving of mathematical equations with several unkowns. There must be as many independent equations as unknowns. In sensorics this means: one additional but slightly different sensor is required for each interfering compound. The task then becomes one of solving n equations for n unknowns, which can be accomplished with an algorithm for matrix calculations and an electronic calculator. However, there are several restrictions that limit the use of this compensating technique.

First, the interfering components must be known in advance so that one can prepare a set of calibration mixtures for obtaining the individual analytical functions for each sensor under variable interference (matrix) concentrations. The approach is therefore limited to a closed sample location, and it presupposes complete information regarding potential interferents within the volume in question. This may prove applicable in certain production control situations, but certainly not in cases where the sample matrix is not sufficiently known a priori, as in the case of most environmental and some clinical analyses. Such precautions cannot be circumvented even with the use of the most sophisticated modern approaches to pattern-recognition analysis and/or so-called adaptive neural-network treatment. All potentially interfering compounds must be known in advance and introduced into the array under study during the so- called learning phase through a permutation of all possible types of mixtures. If for example one analyte is to be determined in a concentration range of 1 to 100 ppm and only five interfering compounds in a similar concentration range are present, and the concentration range should be checked for linearity by five concentrations between 0 and 100 ppm one has a permutation power of about a faculty of 10. Much time may be consumed in the preparation of the necessary mixtures and in performing all the measurements. In the end, the drift associated with most sensors and the limited lifetimes of biochemical sensors could render the whole procedure meaningless!

Second, the linearity and true independence of all effects cannot be guaranteed. In some cases of only one sensor poisoning (e.g. catalyst poisoning) all analytical functions (selectivities and sensitivities) obtained during prior calibration and/or learning are rendered invalid for every individual sensor. How is a sensor array to distinguish between irreversible poisoning effects and the normally reversible disturbances attributable

to ordinary interferents? How should it differentiate between the effects of a positive error (where a portion of the signal is due to interferents) and general matrix effects resulting in diminished sensitivity? Especially in environmental trace analysis (<10 ppm) each sample is very likely to contain more than ten interfering compounds. Intimate knowledge of each, as well as the availability of appropriate standards to permit extensive permutation at various concentrations presupposes the preparation of countless mixtures to be utilized in the training process for the sensor array. It must also be recognized that even trace amounts of certain compounds may totally disrupt the analyte recognition process.

Taking all this into consideration, as well as the fact that most chemists lack fundamental experience with sensor arrays in real open-environmental trace analysis, considerable caution is warranted with respect to this approach to increasing the selectivity of sensors and correcting for interferants. In general, application of a simple and rapid preliminary separation step will be more productive with respect to the goal of achieving a reliable analytical result. Literature examples of successful sensor-array applications related to the identification of beverages or the characterization of odors [340–342] should not be extrapolated to the quantitative analysis of a single analyte. Many of the sensor-array applications (just identification) described in the literature [343–351] involve problems that could have been solved by much simpler means, such as exact density measurement, possible now with extreme accuracy. Differentiation among various samples with similar compositions in the context of a closed system (i.e., without the variability associated with an open matrix) can usually be achieved more economically on the basis of simple physical measurements. Nevertheless, electronic noses and tongues on the market have found some application despite the humidity interference of the first category in certain food processing processes, in which they sense any deterioration in the process (e.g., a rotten tomato in ketchup processing or a bad coffee bean in the roasting process. For those applications in the gas phase the ICB Muenster recently introduced a novel electronic nose based on the new sensor class of conductometric gas microsensors (polymer + plasticizer + organic salt). It has already been mentioned that the permutation of polymer, plasticizer, and organic salt together with their concentration allows the construction of an indefinite number of different membranes with different selectivities. This is shown in Figure 73.

The identifying power of an array of only five of such sensors is shown in Figure 74 [144], [352]. The intended application area was the detection of BETX (benzene, ethylbenzene, toluene and the different xylenes) near gasoline stations for reasons of industrial hygiene. The advantages of this electronic nose using only one type of sensor principle is the low energy consumption (conductivity measurements at room temperature) making hand-held devices feasable and the fast exchange of the sensor array in the form of a cheap sensor card not larger than a business card [353].

Figure 73. General composition of gas selective conductometric polymer membranes (A) and selectivity pattern against several organic solvents (B)

The above mentioned electronic nose was further improved by incorporating an extremely fast enrichment and water elimination step (in the seconds range) and increasing the resolving power following the time course of a fast ther-

mal desorption step. Since the air sampling time, the desorption time and the number of conductometric gas sensors can be individually set, a very versatile and extremely sensitive electronic nose (called: Air-Check) with sensitivities in the ppb range and almost no interference by humidity was developed in the ICB Muenster. It will be positioned in clean rooms for the purpose of surveillance.

3. Biochemical Sensors (Biosensors)

3.1. Definitions, General Construction, and Classification

Biosensors are in general small devices based on a direct spatial coupling between a biologically active compound and a signal transducer equipped with an electronic amplifier (Fig. 75). This definition of an I.U.P.A.C. working group is unfortunately very specific. The crucial thing here is the demand for a "direct spatial coupling" of biomolecules and transducers. This might have influenced the development of further commercial available biosensors since much time has been spent on biomolecule immobilization and stabilization oriented towards biosensors that could be transported and stored without a need for a refrigerator. The intimate contact of the less stable biological recognition element with a transducer surface requires either one shot devices and throwing both away after one deteriorates or a reproducible surface rejuvenation with the biological receptor by the user. The latter is the problem since the user is not an expert in controlled coverage of surfaces. Concerning the life and working time and ease of exchanging the more labile biological recognition element, devices which separate the recognition space from the detection space show certain advantages though they cannot be named a biosensor. It is, e.g., quite feasible to employ the labile biomolecules with or without the required cofactors or reagents in a freeze-dried state in a cartridge to be activated only shortly before its use. This cartridge is then to be used upstream of an optical, electrochemical or calorimetric flow through cell. Keeping this cell for longer use allows more sophisticated constructions. With modern microsystem technology the whole device could be rather small and difficult to visualize at a first glance in that the demanded intimate contact for being a biosensor is missing.

Biological systems at various levels of integration are used to recognize a particular substance that is to be determined in a specific way. Different types of biologically sensitive materials can be used for selective recognition, including enzymes, multienzyme systems, organelles, photosensitve membranes from plants and bacteria, membranes generally, protoplasts, whole intact cells, tissue slices, antibodies, lectins, DNA, and transport protein or receptor systems isolated from cell membranes. The macromolecular biological compound is ordinarily immobilized in close proximity to the transducer surface, thereby facilitating direct or mediated sig-

Figure 74. Identifying important BETX compound in the ppm range with only five conductometric gas sensors (ICB-Muenster patent) via principal component analysis (PCA), preliminary results [352]

nal transfer to the transducer. Besides fixing the receptor on the transducer surface this immobilization also serves the important function of stabilizing the biological material.

Table 17. Transducer systems used in the design of biosensors

Transducer	Indicating a change in:	Caused by :
Amperometric electrodes	electron transport	enzyme-catalyzed oxidation or reduction of an analyte
Potentiometric electrodes, ISFETs, MOSFETs, conductometric devices	ion concentration	enzyme-catalyzed oxidation, hydrolysis, or cleavage of C – C, C – O, C – N, or other bonds
Calorimetric devices (thermistors, thermopiles)	enthalpy	enzyme-catalyzed reactions
Piezoelectric crystals	mass	bioaffinity reaction (between Ab – Ag, Ab – hapten, an analyte and receptor protein, or analyte and lectin
Fluorometric fiber optics	fluorescing concentration of enzyme substrates/products or immunolabels	enzyme and bioaffinity reactions
Waveguides	optical path (adlayer)	bioaffinity reaction
Devices based on surface plasmon resonance	resonance (adlayer)	bioaffinity reaction

The first indicating step is specific complex formation between the immobilized biologically active compound (in a broader sense, the receptor R) and the analyte (A). This selective and usually reversible interaction produces secondary chemical or physical signals that are recognizable by a suitable electrochemical, optical, enthalpimetric, conductometric, or piezoelectric transducer. The transducer of choice depends on the nature of the molecular-level binding affinity with respect to the analyte, which may cause changes in such parameters as the redox state of the receptor compounds, the concentrations of electrochemically or optically active substances that are consumed or produced, or heat, mass, or electromagnetic radiation (see Table 17) [354–357].

Depending upon the mechanism of biochemical interaction between the receptor and the analyte, two basic types of biosensors can be distinguished: *biocatalytic* (metabolic) sensors, and *bioaffinity* sensors (Table 18).

Among the analytes detectable with biosensors are carbohydrates, organic acids, alcohols, phenols, amines, heterocyclic compounds, proteins, enzymes, cofactors, inorganic ions, hormones, vitamins, peptides, drugs, xenobiotics, microorganisms, gases, and pesticides. Analyte concentrations measurable with various types of biosensors range from $10^{-7}\,\mathrm{mol\,L^{-1}}$ (biocatalytic sensors) to as little as $10^{-15}\,\mathrm{mol\,L^{-1}}$ (affinity sensors). Based on their level of integration, biosensors can be subdivided into three generations:

1) *First Generation.* The receptor is entrapped between or bound to membranes, and the combination is fixed on the surface of an appropriate transducer or known chemical sensor .
2) *Second Generation*. The receptor is bound covalently to the transducer's surface, thereby eliminating the need for a semipermeable membrane.
3) *Third Generation*. The receptor is bound to an electronic device that transduces and amplifies the signal (e.g., the gate of a field-effect transistor, an array of amperometric ultramicroelectrodes, or interdigitated microelectrodes), utilizing the techniques of microelectronics and micromechanics.

It should be mentioned that this classification is not also meant to be an order of increasing performance. In general rugged systems have more advantages than complicated and expensive constructions.

3.2. Biocatalytic (Metabolic) Sensors

Metabolic biosensors are based on the specific recognition of some enzyme substrate and its subsequent chemical conversion to the corresponding product(s). The biocatalytic reaction itself accomplishes specific binding between the active site of the enzyme and the substrate

(recognition process), conversion of the substrate to product, and release of the product from the active center, which in turn leads to regeneration of the binding affinity and catalytic state of the enzyme.

Figure 76. Configuration of an amperometric enzyme electrode for glucose determination

The linear measuring range for metabolic sensors depends on the "apparent" Michaelis–Menten constant (K_{Mapp}) of the immobilized enzyme (not free in solution and approachable from all directions, thus, "apparent"), which describes a particular substrate concentration associated with half the maximum rate of the enzyme reaction. The reaction rate of an immobilized receptor enzyme is controlled by the rate of substrate and product diffusion through both the semipermeable membrane covering the enzyme and the layer of immobilized enzyme itself, resulting in a higher K_{M} value than that anticipated under conditions of kinetic control. Enzymes, coupled enzyme sequences, organelles, microorganisms, or tissue slices can all be used as receptor materials for metabolic sensors. Under certain conditions, cosubstrates, effectors (inhibitors, activators), and enzyme activities can also be determined by metabolic sensors.

3.2.1. Monoenzyme Sensors

Enzyme sensors rely on an immobilized enzyme as the biologically active component. Many biocatalytic reactions, especially those of oxidoreductases, hydrolases, and lyases, are associated with the consumption or formation of electroactive substrates or products in concentrations proportional to the analyte concentration. For this reason most commercially available biosensors are enzyme sensors based on electrochemical transducers.

Typical electrochemically detectable (co-) substrates and products include oxygen, hydrogen peroxide, hydrogen ion, ammonia, carbon dioxide, reduced or oxidized cofactors, and redox-active (oxidized or reduced) prosthetic groups in oxidoreductases, all of which can easily be converted into electrical signals by suitable transducers (e.g., amperometric or potentiometric electrodes or conductometric sensors, Table 19).

Immobilization of an enzyme in or at an artificial matrix or a membrane usually stabilizes the biocompound, thereby increasing the half-life for activity. Techniques of enzyme immobilization include physical or chemical adsorption, ionic and covalent bonding (perhaps to functionalized transducer surfaces), cross-linking by bifunctional agents, and entrapment in such polymer matrices as natural or artificial gels and conducting polymers. The first biosensor was described by Clark and Lyons in 1962, who introduced the term "enzyme electrode" [358]. In this first enzyme sensor, an oxidase enzyme in a sandwich membrane was placed next to a platinum redox electrode. A platinum anode polarized at +0.6 V (vs. SCE) responded to peroxide produced by the resulting enzyme reaction with the substrate. Application of a polarization voltage of −0.6 V permitted the amperometric detection of oxygen consumption. The primary target substrate was β-D-glucose (Fig. 76). Stoichiometric turnover of the glucose oxidase-catalyzed reaction yields a sensor response proportional to the glucose concentration up to the apparent K_{M} value of the immobilized enzyme. This in turn led to the first glucose an-

alyzer for measuring glucose in dilute blood on the basis of an amperometric enzyme sensor. A commercial analog, the Yellow Springs Instrument Model 23 YSI, appeared on the market in 1974. The same indicating technique has more recently been applied to many other oxygen-mediated oxidase systems, which constitute the most widely exploited enzyme classes for the construction of biosensors.

Figure 77. Operating principle of a mediator-modified amperometric biosensor, involving an oxidase or a dehydrogenase (in the case of a reductase, electron transfer would proceed from the electrode to the analyte substrate)
a) Amperometric enzyme sensor; b) Mediator-modified electrode; c) Redox electrode

Amperometric Biosensors Using Artificial Electron Mediators. Amperometric biosensors for monitoring oxidase-catalyzed oxygen consumption or the production of hydrogen peroxide are, under certain circumstances, restricted in their use because of a limited availability of dissolved oxygen. This may necessitate careful pretreatment of the sample with rigorous exclusion of oxygen-consuming compounds, as well as application of a high polarization voltage, which may cause interfering currents in complex matrices.

It should be possible to overcome such problems by direct electron transfer between the redox-active prosthetic group of an enzyme and the electrode surface. In a few cases, especially ones involving small redox proteins such as cytochrome c, efficient electron transfer has been achieved in this way with promoters that direct the active redox centers to the electrode surface. Macromolecular redox proteins exhibit rather low rates of heterogeneous electron transfer because according to the Marcus theory tunneling is not possible over the long distance from the active center to the electrode surface. Thus, the transfer is often accompanied by a large overpotential, but the use of redox mediators may increase the electron-transfer rate dramatically. These low-molecular-mass (in)organic redox species undergo facile reversible redox reactions with both the prosthetic groups of the enzyme and the electrode surface according to the general scheme depicted in Figure 77. The resulting electron shuttle reduces the overvoltage of the biological redox system to the formal potential of the mediator. Suitable redox mediators are redox systems which show a high exchange current density and include quinoid redox dyes,

quinones, organometallic compounds, and fulvalenes (see Table 20) [359–363].

Table 19. Common configurations for monoenzyme sensors

Enzyme class	Detectable compound involved in the enzyme reaction	Typical transducer
Oxidoreductases		
Oxidases	O_2, H_2O_2	pO_2 electrode, noble-metal – carbon redox electrode
Oxygenases	O_2, quinones, catechol	pO_2 electrode, (amperometric) carbon electrode
NAD(P)-dependent dehydrogenases	NAD(P)H/NAD(P)	(amperometric) mediator-modified redox electrode, fluorometer, photometer
PQQ-dependent dehydrogenases	PQQ/$PQQH_2$	
Reductases	NAD(P)H/NAD(P) Heme-, Cu-, Mo-, FeS-containing centers	
Hydrogenases	H_2, NAD(P)H, NAD(P), $FADH_2$, $FMNH_2$, FeS-, Ni-containing centers	
Hydrolases	NH_3/(NH_4)	(potentiometric) ammonia-sensitive electrode
	CO_2	(potentiometric) pCO_2 electrode
	H^+	pH electrode, ISFETs, coulometer, conductometric and enthalpimetric devices
	redox-active products (phenolic, thio-group-containing compounds)	(amperometric) redox electrodes

In constructing such a biosensor the redox mediators can be immobilized at the electrode surfaces in various ways, including chemisorption or covalent bonding, chemical or physical deposition of a polymer film containing the mediator molecules, or physical incorporation of the redox mediators (which are only slightly water soluble) directly into the electrode material. One ingenious approach involves covalent binding of the mediator to the electrode via an appropriate *spacer*, or electrical "wiring" of the enzyme through an electron-relaying redox polymer network. In both cases electron transfer from the redox centers to the electrode surface is thought to occur by electron tunneling [364–366]. The use of a redox mediator increases the dynamic range of a sensor, minimizes interferences, and provides an indicator reaction that is usually independent of the oxygen content of the matrix. Furthermore, such mediators undergo reversible redox reactions with redox-active coenzymes, dehydrogenases, reductases, and hydrogenases, as well as the redox-active products of enzyme- catalyzed reactions, which opens many new possibilities for incorporating these classes of oxidoreductases into new types of biosensors.

3.2.2. Multienzyme Sensors

Coupled enzyme reactions mimic certain metabolic situations in organelles and cells that have themselves already been exploited in biosensors [367], [368]. The use of enzyme sequences facilitates:

1) Broadening the scope of detectable analytes
2) Improving selectivity
3) Increasing both sensitivity and dynamic range
4) Eliminating interferences

Depending on the target analyte, sample matrix, required measuring range, etc., enzymes can be coupled to produce reaction sequences operating either in series or in parallel. An alternative approach to realizing multienzyme sensors is the use of cell complexes, whole cells, or tissue slices comprising physiologically integrated enzyme systems (see below).

Enzyme Sequences Operating in Series. The number of substances that can be determined directly by monoenzyme sensors is limited, because many enzyme- catalyzed reactions involve no physicochemically detectable substances. To form readily detectable compounds it is often necessary, therefore, to couple together several different enzyme reactions in a sequential way. The analyte of interest is first converted by some specifically catalyzing enzyme into a product that is itself convertable in the course of one or more subsequent enzyme reactions involving detectable secondary (co)substrates or products. Biosensors based on such enzyme sequences have been developed for the determination of many substrates, including disaccharides (sucrose, maltose, cellulose, lactose), cholesterol, creatinine, and nucleic acids [356].

With certain enzyme sequences it is possible to achieve chemical signal amplification

Table 20. Redox mediators leading to efficient electron transfer with redox proteins

Mediator type	Examples	Structures
Quinones	benzoquinone	
Quinodimethanes	tetracyanoquinodimethane (TCNQ)	Tetrathiafulvalene (TTF) and its derivatives		Metallocenes and their derivatives	ferrocene	Phthalocyanines (Co, Fe, Mn, Cu)	cobalt phthalocyanine (Co-PC)	Quinoid redox dyes		
Phenazines	*N*-methylphenazonium (NMP^+) salts	Phenoxazines	meldola blue	Phenothiazines	methylene blue	Indamines	toluylene blue	Viologens	methyl viologen	Complex compounds		
Ruthenium complexes		$[Ru(NH_3)_6]^{3+/2+}$, $[Ru(en)_3]^{2+/3+}$
Osmium complexes		$[Os(bpy)_2Cl]^{3+/2+}$
Cobalt complexes		$[Co(bpy)_3]^{3+/2+}$, $[Co(en)_3]^{2+/3+}$
Iron complexes		$[Fe(CN)_6]^{3+/4+}$, $[Fe(phen)_3]^{2+/3+}$

through the accumulation of a particular product by cycling the substrates or cofactors. The sensitivity of some biosensors can be enhanced in this way by as much as three orders of magnitude. Signal-amplifying enzyme systems have been based on oxidase – dehydrogenase, dehydrogenase – transferase, and phosphorylase – phosphatase – oxidase sequences, permitting the determination, for example, of lactate, ATP, and phosphate at the picomole per liter level (Fig. 78) [357–369].

Enzyme Sequences Operating in Parallel. Multienzyme sequences operating in parallel are used for the elimination of interfering agents, expansion of the dynamic measuring range, and (in principle) the indirect detection of an electrochemically inactive reaction catalyzed by one of the enzymes in a substrate competition. *Anti-interference* enzyme systems are the most important. Substances interfering with an indicating reaction can be eliminated as one way of improving the analytical quality of the measurement by covering the immobilized enzyme with an anti-interference enzyme layer, in which a second enzyme converts the disturbing substance into an inert product. This strategy has made it possible to remove such interfering agents as ascorbic acid and endogenous glucose [367].

Biosensors Based on Integrated Biological Enzyme Systems. Cellular organelles and membranes, as well as whole cells or tissue slices from animal or plant sources comprising physiologically coupled multienzyme systems are often employed as receptor materials in biosensors based on electrochemical detection. Native physiologically integrated enzyme systems display enhanced stability due to their in vivo environment. Biological material of this type offers the potential for low cost and simple preparation. Furthermore, this opens the way to analytes that are converted to electrochemically detectable products not by simple enzyme reactions, but rather by complex multienzyme reactions within an intact biological structure. Analytes subject to such receptor systems include chloroaromatics, caprolactam, naphthalene, tryptophan, several hormones, and acetic acid [354], [370].

3.2.3. Enzyme Sensors for Inhibitors – Toxic Effect Sensors

Sensors for inhibitors are based on competitive inhibition between a substrate and an inhibitor for an enzyme binding site, inhibition of an enzyme reaction by product accumulation, irreversible binding of an inhibitor to an active binding site, or redox-active heme or SH groups of enzymes that lead to the blocking of enzyme activity.

When thylakoid membranes, protoplasts, or whole cells are used as receptor materials, various inhibitors cause metabolic "short circuits," or inhibition of the (photosynthetic) electron-transport system, which results in a decrease in such metabolic parameters as oxygen consumption or production, photocurrent development, dehydrogenase activity, or fluorescence. In contrast to metabolic sensors, the first sensing step here is a result of binding of the inhibitor to an active binding site or redox center on the enzyme. Sensors of this type usually operate at low enzyme-loading factors and with substrate saturation in order to ensure a highly sensitive signal of limitation in the kinetically controlled reaction due to the presence of an inhibitor. Examples of such inhibitors (analytes) include toxic gases, pesticides, chloroorganic compounds, phenols, and heavy-metal ions [371], [372]. To detect toxic effects on vital enzymes in a reproducible manner, to include also synergistic or antagonistic effects, is only possible with biosensors or bio-tests. This advantage as a fast warning device is still not fully used. Too often biosensors are developed as if they should compete with instrumental analysis. Given the pace of development in this area, especially concerning miniaturization, speed, and versatility, the biosensor as a mono-analytical device will have problems in gaining a larger market share. However, as a toxic warning device triggering some screening and sampling it is without competition.

3.2.4. Biosensors Utilizing Intact Biological Receptors

Molecular receptors are cellular proteins (often membrane-bound) that bind specific chemicals

Figure 78. Enzyme sequence for the detection of inorganic phosphate, based on the principle of chemical signal amplification [369]
a) Dialysis membrane; b) H_2O_2/O_2 permeable membrane; d) Working electrode

in such a way as to produce a conformational change in the protein structure. This conformational change in turn triggers a cellular response: opening of an ion channel, for example, or secretion of an enzyme. In general, molecular receptors can be distinguished from other types of receptors (including larger multicomponent systems) on the basis of their composition, which is a single protein, though this protein may contain more than one subunit. Among the important receptors known to date are receptors for hormones (control agents for a wide range of cellular and body functions), amino acids, insulin, and neurochemical transmitters, in addition to receptors capable of binding synthetic bioactive chemicals, such as drugs [373], [374].

Molecular receptors have two important properties relevant to their possible incorporation into biosensor devices: intrinsic signal amplification and high specificity. The specificity is a consequence of a highly evolved binding region within the receptor that is fully optimized for binding one particular ligand by a variety of electrostatic, hydrogen bonding, van der Waals, and hydrophobic forces.

Limitations affecting the study and use of molecular receptors include:

1) Relatively difficult experimental procedures for the isolation of the receptor proteins (even prior to purification), which are both time- consuming and expensive, and often require animal sources
2) An absence of techniques for obtaining more than very small amounts of pure receptors
3) The rapid loss of biological function that usually follows isolation

Molecular biology has brought considerable progress in the isolation and purification of receptors, while advances in artificial membrane technology and reconstitution have reduced the problem of instability.

Comparatively few biosensors of this type have been reported [373], [374], primarily because of problems associated with the successful isolation of molecular receptors (in sufficient quantity and purity) and their subsequent stabilization in artificial environments in such a way that appreciable biological activity is retained.

A clear exception, however, is a fiber-optic sensor based on evanescent fluorescence developed by Eldefrawi et al. [374], [375] that contains nicotinic acetylcholine receptor (nAChR). This was the first neurotransmitter receptor to be purified and characterized in vitro, and it is involved in chemical signalling. The sensor in question consisted of nAChR immobilized on the surface of a quartz fiber. Determination of the concentration of acetylcholine and other natural neurotransmitters (e.g., nicotine) was accomplished by measuring the extent to which they inhibited the binding of a standard solution of a fluorescence-labeled toxin (fluorescein isothiocyanate-α-bungarotoxin, FITC-α-BGT). Binding determinations were based on measurements of fluorescence intensity in the

region of the evanescent wave (that is, at the fiber – solution interface, see Section 2.3.2.1), where the nAChR was immobilized. The sensor had an acceptable signal-to-noise ratio of 10^2 and an analysis time < 10 min (based on the initial rate of signal increase rather than a steady-state value), and it was capable of operating under conditions of high ionic strength. However, it suffered from the problem of non-regeneration of the sensing element because of the irreversibility of FITC-α-BGT binding to the nAChR.

A similar receptor-based biosensor using electrochemical detection was reported for the detection and measurement of riboflavin (vitamin B_2) [373], [374]. This device is based on the competition for aporiboflavin-binding protein (apoRBP) between riboflavin present in the sample subject to analysis and a riboflavin analogue bound in a membrane. In the absence of riboflavin all the apoRBP is bound to the analogue on the membrane. When riboflavin solution is added, the five-fold greater affinity of apoRBP for its natural cofactor (riboflavin) results in displacement of apoRBP from the membrane into the solution, causing a change in the electrical potential of the membrane. A riboflavin measurement range of $0.1 - 2 \times 10^{-6}$ mol/L was reported.

Further progress in molecular receptor-based sensors will be a function of advances in molecular biology with respect to enhancing the quantity, purity, and stability of receptors that can be used in vitro.

3.3. Affinity Sensors – Immuno-Probes

Affinity sensors take advantage of physicochemical changes that accompany complex formation (e.g., changes in layer thickness, refractive index, light absorption, or electrical charge). Once a measurement has been made the initial state must be regenerated by splitting off the complex. Because of this they cannot be used for continuous monitoring nor to follow declining concentrations of the analyte. Therefore, they cannot be named biosensors into the strict sense of the I.U.P.A.C. definition to be "reversible". Thus, they are named immuno-probes. Since the splitting of the complex can be very fast (e.g., with pH < 2.0 or chaotropic reagents) and with the process being automated (e.g., in FIA-systems) the response time of an immuno system can reach less than 1 min and, thus, becomes comparable to enzymatic biosensors working under diffusion control.

Examples include immunosensors utilizing antibodies or antigens for recognition purposes, lectins, and "true" biological receptors in matrix-bound form (see Section 3.2.4).

Immunosensors Based on Antibody Molecules. Biosensors based on the antigen – antibody interaction are called *immuno-probes.* The high specificity and high sensitivity that typifies an antigen – antibody (Ag – Ab) reaction has been used in a vast range of laboratory-based tests incorporating antibody components (immunoassays). The analytes detected and measured have included many medical diagnostic molecules, such as hormones (e.g., pregnancy-related steroids), clinical disease markers, drugs (therapeutic and abused), bacteria, and such environmental pollutants as pesticides. A crucial distinction must be made between an immunoassay and an immuno-probe, however, with respect to the technology relevant to the analysis. The ultimate aim is a low-cost, disposable immuno-probe, with the entire device being used only once. For example, it has now proven possible in practice to develop an instrument containing a disposable "sensor chip" that can be used for Ab or Ag tests.

Two different types of immuno-probes have been described:

1) *Direct immunosensors* register immunochemical complex formation at the transducer surface via electrochemical, mass or optical changes. The advantage of a direct immunosensor is that measurement of the antigen – antibody interaction can be accomplished immediately without any need for additional antibodies or markers (enzymes, fluorescent labels, etc.).
2) *Indirect immunosensors* are based (like homogeneous and heterogeneous immunoassays) on labeling of one of the partners in an immune interaction. One class of indirect immunosensors derived mainly from enzyme immunoassays (EIA) encompasses the enzyme immunosensors. These combine the

high selectivity of an immunoreaction with the high sensitivity characteristic of the enzymatic amplification effect. However, the enzyme can affect the molecular recognition step because of its large size and needs in general special attention (cooling) during storage. In the case of the widely used assay technique of Enzyme Linked Immuno Sorbent Assay (ELISA) the use of enzymes generates two further manipulations: a) the addition of a suitable sustrate and b) the addition of a reagent which stops the enzymatic reation. This is not necessary when using modern fluorescence markers.

(with permission from GEC Journal of Research, Essex)

3.3.1. Direct-Sensing Immuno-Probes without Marker Molecules

Among direct immunosensors the most favored are optical sensors, because they incorporate the advantages of fiber optics or optoelectronic transducers. The nonelectrical properties of optical systems offer important safety advantages for medical, industrial, and military applications. Remote sensing is clearly advantageous, for example, for explosives and toxins. Optical-fiber probes are also mechanically flexible, small, inexpensive, and disposable.

The detection of an evanescent field in an optical waveguide (see Section 2.3.2.1) is a highly sensitive technique especially suitable for monitoring the antibody – antigen interaction [373], [374]. One partner of the immuno pair (e.g., the antibody) is immobilized at the surface of the waveguide, and its reaction with the other partner in the test sample is monitored. An evanescent wave generally penetrates a distance of several hundred nanometers extending the full length of an antibody – antigen complex, so in contrast to conventional techniques there is no need to carry out a prior separation of the nonspecific biological components. There is no need for washing steps.

The technique of surface plasmon resonance (SPR) represents a very sensitive way to follow an immuno-reaction on an interface , and its feasibility has been adequately demonstrated [376]. As noted previously (Section 2.3.2.3), SPR is a phenomenon produced by a beam of light directed onto a glass – metal interface, usually a glass prism in contact with a layer of gold or silver (Fig. 79). At some specific angle (the resonance angle) a component of the electromagnetic light wave propagates in the metal along the plane of the interface, taking the form of surface plasmons. The resonance angle is quite sensitive to changes in refractive index and dielectric constant at the interface up to a distance of several hundred nanometers from the actual metal surface, with the sensitivity decreasing exponentially as a function of distance from the surface. Immobilization of an antibody on the surface causes a measurable shift in the resonance angle, and binding of a high-molecular antigen to the immobilized antibody leads to a further change. For typical biological systems this binding-induced shift in resonance angle (expressed in resonance units) is approximately linearly proportional to the concentration of bound antigen (or antibody if antigen has been pre-immobilized).

The SPR-based biosensor systems BIAcore and BIAlite, developed by Pharmacia Biosensor AB and now available commercially, represent a breakthrough in immunosensor technology, particularly in the use of SPR techniques. Apart from high cost, the only limitation associated with this technique is that the sensitivity depends on the molecular mass of the adsorbed layer, which in turn controls the optical thickness, so low concentrations of small molecules (molecular mass < 250, including most haptens) are unlikely to be measurable directly without additional labeling. In

addition to SPR, Mach–Zehnder interferometers [377], RIFS [201], [202], and so-called grating couplers [378] are also used for optical immunosensing. An interesting step towards miniaturization was introduced by the development of practicable fiber optical SPR systems by Jorgenson and Yee [379] and Katerkamp et al. in the ICB Muenster [380], [381]. The latter device was so small and low-cost that application as a hand-held refractometer with a resolution in the fifth digit after der decimal point was feasible. The fiber optical SPR tips were rapidly exchangeable and bending of the fiber had no negative influence on the result.

All the above mentioned transducers measure changes in the refractive index and layer thickness together! With respect to quantitative assays one should bear in mind that those techniques only sense a mean layer thickness. Thickness extensions that occur because of large macromolecules are leveled out. Futhermore, the change of the refractive index inside the evalescent field (within the surface layer) may also depend on ions or water molecules entrapped in the proteins. The latter is dependent on the ionic strength. Thus, changes in the ionic strength of the sample solution may also produce a signal. In addition, if antibody molecules are immobilized on the transducer surface, how can anyone differentiate between an immunoreaction with the analyte or a change in the tertiary and quarternary structure of the antibody molecule caused by other effects giving rise to a change in the thickness of the layer?

Alternative transducer technologies that have been applied in immunosensor research include piezoelectric and electrochemical systems. *Piezoelectric* immunosensors [383], [384] (see Section 2.3.3) tend to suffer from significant levels of nonspecific binding to the piezoelectric substrate, which makes accurate analyte quantification difficult. However, this type of immunosensor may have an important role to play in the search for traces of volatile drugs in security monitoring, and it offers the advantages of relatively small size and low manufacturing cost. The main disadvantage from the standpoint of immunosensing is that reproducible measurements have so far been achieved only in the gas phase, whereas the Ab–Ag interaction is restricted to aqueous solution. As has already been mentioned above, working with mass-sensitive transducers in liquids gives rise to doubts about the correct interpretation of frequency shifts. Here, the same as in case of the optical transducers, they need to be differentiated from real mass changes. Any structural changes of large protein molecules which induce associated changes of entrapped water and ions will result in a measurable signal. Despite the fact that these frequency changes have nothing to do with specifically bound analyte molecules these signals can be very reproducible. Without a thorough and convincing validation with real samples, the analytical accuracies are questionable. This is not to say that qualitative binding studies or determination of association constants could not be measured. All transducers needing no label compound are ideal for screening purposes. They are mostly used for the detection of specific receptor functions.

Potentiometric immunosensors [356] (see Section 2.3.1.1) are unfortunately associated with a low signal-to-noise ratio as a result of the low charge density on most biomolecules relative to such background interferences as ions. These sensors also show a marked dependence of signal response on sample conditions, including pH and ionic strength. Similarly, *immunoFET* devices (see Section 2.3.1.4), which measure very small changes in an electric field when an Ab–Ag binding reaction occurs, tend to suffer from practical problems associated with membrane performance and various artifacts. The theoretical basis of the sometimes observed voltage change remains unclear. The only plausible explanation for the fact is that clearly the binding of a neutral antigen molecule to a large antibody molecule with multiple charges (depending on the pH and isoelectric point) may change the charge distribution at the interface or may lead to a different mixed potential. If the whole immuno-reaction producing an analyte proportional signal is not watched carefully and controlled by convincing validation studies, a certain bias can easily be overlooked by all so called direct sensing techniques.

Main Drawback of all Direct Sensing Techniques. It has become a well known fact that the sensitivity (or LOD) of all direct sensing techniques is not any signal-to-noise ratio nor any theoretical mass-loading sensitivity! It is the lack of control over non-specific binding processes, which are not caused by the very

specific molecular interaction under study. All direct sensing immuno-techniques cannot differentiate between competing surface processes leading to adsorbed particles with various heats of adsorption. Even if working with very hydrophilic surfaces to prevent this, the ultimate LOD of such an immuno-probe depends, according to the laws of Analytical Chemistry, on the standard deviation of such non-specific binding (LDO = 3 x σ_{blank})! This renders many extreme sensitive transducers useless for practical applications in real world samples.

Amperometric or fluorescence-based immunotechnology (immuno-electrodes or capillary fill devices with a fluorescence label, for example) has shown more promising results at the research prototype stage than other types of transducers. One preferred technique continues to be the indirect amperometric immunosensor approach described below, which uses enzymes as markers. The second emerging technique is based on fluorescence dyes which are now commercially available together with a simple covalently binding protocol (one to two steps only). Fluorescence can be as sensitive as enzyme-based amperometry especially if modern fluorophores are used with excitation wavelengths in the near IR and the emission shifted about 100 nm to higher wavelengths. Around 600 – 800 nm is an observation window for biological systems since no natural fluorescence (e.g., tryptophane) occurs in that region. Furthermore, cheap laser diodes of around 680 nm with high energy are available.

3.3.2. Indirect-Sensing Immuno-Probes using Marker Molecules

The most satisfactory marker molecules for use in this context have been fluorophores and enzymes. As regards the sensors themselves, several fundamental types exist.

Reactor immuno-systems are based on a cartridge or microcolumn packed with appropriate immobilized antibodies (which serve as so-called catching antibodies). As in the case of enzyme immunoassays, the competition, sandwich, and replacement principles are all subject to exploitation. The amount of bound (or replaced) antigen is determined via the extent of enzyme activity remaining after substrate addition, which can be established with an electrochemical or optical sensor. For many applications (on-line measurements, coupling with flow-injection analysis), repeated and automated measurements are required. Because of the extremely high loading of catching antibodies, reactor immunosensors have the advantages of high sensitivity, regenerability, and reproducibility. On average they can be reused 50 – 100 times without loss of activity. The US Naval Research Laboratories were very successful with respect to sensitivity, selectivity, reliability, and simplicity with several prototypes of reactor-based systems they developed under the guidance of Frances Ligler [382]. The developed immuno-systems allow field determinations and have been extensively tested and validated in the field of environmental analysis. In this respect, it is worthwhile to mention that the US EPA has adopted immuno-kits for certain important analytes in the environment, e.g. gasoline spills. If the fluorophore is carefully selected sensitivities in the ppb range with a FIA-like set-up and response times under 1 min are possible!

Membrane immuno-probes employ antibodies immobilized directly at the surface of a sensor, or at a membrane covering the sensor, as shown in Figure 80. An example of the use of this type of immunosensor is illustrated schematically in Figure 81. The analyte to be detected is an early myocardial infarction marker, the fatty acid binding protein (FABP). A modified Clark electrode is covered by a membrane bearing immobilized monoclonal catching antibodies directed against FABP. After binding of the analyte and washing, a secondary polyclonal antibody is added to the solution. This secondary antibody is conjugated with glucose oxidase (GOD). The next step is incubation followed by further washing, after which glucose is added to the measuring solution. Glucose is oxidized by GOD in an amount directly proportional to the amount of FABP, yielding H_2O_2, the concentration of which is monitored with an amperometric sensor, as shown in Figure 82. This system was developed at the ICB Muenster with the aim of developing a rapid test for a myocardial infarct to be performed actually in the ambulance with only one drop of blood. It works fully automatically. One drawback was, however, the use of a labile enzyme. Despite the fact that GOD was the most stable known enzyme, some pre-

cautions had to be taken and also the need for substrate addition and stopping of the reaction needed computer-controlled timing.

Figure 80. Design principle of an immunosensor system a) Immunosensor; b) Electronic unit; c) Computing unit; d) O-Rings; e) Catching antibody membrane; f) Dialysis membrane; g) Pt vs. Ag/AgCl electrode

One example of a nice commercial immunosensor is produced by Serono Diagnostics. This fluorescence-based evanescent-wave immunosensor [374], [375], [376] incorporates a novel capillary-fill design, and is shown in Figure 83.

The system consists of two glass plates separated by a narrow capillary gap of 100 mm. The lower plate acts as an optical waveguide and contains on its surface an immobilized layer of antibodies. The system benefits from its capillary-fill system, by means of which a fixed volume of sample is drawn into the space between the plates regardless of the volume of the bulk sample (a blood droplet for example). Delivery of a highly reproducible volume of sample eliminates a significant source of error in analyte measurement. The Serono immunosensing format constitutes a competitive assay, though a sandwich-type assay could also be used. The upper plate contains on its surface a layer of fluorescence-labeled analyte trapped in a water-soluble matrix. On addition of sample the labeled analyte is released into solution, where it competes for antibody sites on the lower plate with any unlabeled analyte present in the sample. After a fixed incubation period the fluorescence signal of the evanescent waves is measured and related to analyte concentration.

Figure 82. Analytical results obtained with the human heart FABP sensor described in Figure 81 as a function of time after onset of a myocardial infarction

This technology does have shortcomings, however, some of which are related to the practical problems associated with carrying out measurements on whole blood. These include poor capillary flow because of the "stickiness" of blood compared with water, increased incubation time resulting from slow dissolution of the labeled analyte matrix, and the presence of fluorescent and highly colored molecules in blood, such as hemoglobin. Drawbacks include the necessity for an incubation period of several minutes (due to Ag – Ab interaction) and increased manufacturing costs (each analyte to be tested requires a dedicated sensor, which involves labeling and immobilization prior to physical construction).

While immunological analysis with one of the different ELISA methods works very well and reliably in the laboratory, the fabrication of pre-calibrated small stick-like probes has usually failed until recently. The main problem was the lack of information one has about the surface density of active immunopartners and a way of reproducibly manufacturing those single-use devices with antibodies or analyte molecules

Figure 83. Principle of the patented Capillary-Fill Device. The upper part shows schematically a competitive immuno-assay; the lower part a sandwich assay. The optical waveguide is always the lower baseplate. Here a diode laser beam is used to produced an evanescent field in the sample inside the capillary.

bound to the surface. Thus, one or more calibration solutions to be run simultaneously on all surfaces with immobilized biomolecules were always necessary. Only if full control of the surface density and state (active or not, freely accessible or not, etc.) were be given pre-calibrated immuno-probes for such fields other than clinical diagnostic and environmental field analysis with quantitative results would be feasible.

The Integrated Optical System – IOS. The solution to overcoming the main drawbacks of all hitherto developed biosensors, with the exception of the glucose sensor (poor storage capability), is a single-use sensor chip on which the labile biomolecules could be kept active forever by freeze-drying them. The solution to overcoming the pre-calibration problems is to employ a kinetic data evaluation method. The solution to overcoming the mostly diffusion limited immuno-reaction at an interface is to reduce the Nernstian diffusion layer thickness significantly so that differences in the association kinetics become apparent. To overcome poor sensitivity the solution is to use stable fluorophores with high quantum yield and emission in the near IR. In order to overcome washing steps, the evanescent field method for excitation and back-coupling has to be employed used. The IOS-chip (developed at the ICB Muenster) consists of a plastic baseplate with a refracting index of about 1.50. The mostly aqueous samples lie in the range of about 1.33. Thus, if the interface plastic base sample solution is illuminated, total reflection takes place and the light is reflected back into the plastic chip material. However, the reflected light does not fall abruptly to zero in the sample phase but fades exponentially (evanescent field). The evanescent field reaches out into the sample medium only about 100 nm. The first 20 nm contain about 20 % of the optical power radiated onto the interface. The dimensions of most antibodies lie in a range between 5 and 7 nm. This means that only those fluorophore-labeled antibodies that are located directly on the surface are excited to fluorescence. Labeled but not specifically bound antibodies in the sample volume above the interface are not excited. Together with further improvements the IOS technology was patented wordwide by the ICB Muenster (prior art: DE 19628002 A2/DE 19711281 A2 inventors: Katerkamp, Meusel, Trau).

The plastic base chip, onto which a diode laser beam (λ near the absorption wavelength of the fluorophore) is located, is directed from underneath. The corresponding antibodies or antigens are immobilized on the chip (about 30×10 mm) surface in a simple and straightforward batch process of several thousands or more. Then, in order to reduce the Nernstian diffusion layer thickness a very thin double adhesive spacer (about 50 µm or lower) and a cut-out sample flowing channel is put onto the side with the immobilized molecules. A plastic cover with two openings for the sample in- and outlet is put on forming the necessary narrow detection channel for the hydrodynamics. The sample is brought into the measuring channel by suction forces applied at the outlet within the apparatus. However, on the sample inlet side of the chip, an easy to change container (dwell) is located. On its wall all necessary reagents, buffer, etc. are freeze-dried. The type of recognition molecule is determined by the method. In general all known ELISA methods are feasible with higher speed and sensitivity. Of particular interest are generic chip designs in which, e.g., a labelled antibody (e.g., with a Cy5 kit) reacts with the antigen of the sample in the small dwell at the inlet and is then filtered into the latter via a membrane filter with immobilized antigen. Thus, the excess antibodies are not passing through since they are captured on the filter surface. However, the antigen – antibody complex reaches the optical channel after application of a slight vacuum on the outlet side. Here a catching layer for general antibody recognition makes the whole device generic! The dynamic measurement of the slope of the increasing fluorescence signal falling onto a simple optical detector below the chip is important. In the described operational mode this slope strictly depends on the concentration of the antigen. This slope can be measured in a few seconds! In cases of extremely low levels, the measuring time can be increased. By this kinetic evalution and viewing of the whole active area the inactivation of receptor molecules on the surface is more or less evened-out. The slope depends much more on the concentration of the partners and the constant hydrodynamics.

This IOS technology has recently been licensed to several companies in the field of diagnostics and will change the future of biosensing because of its inherent advantages:

- no washing and separation steps are needed for performing solid phase immunoassays in this arrangement
- reduction in measuring time from several hours to a few seconds
- dramatic increase in sensitivity (< ppb)
- automatic computer control of the whole process:
  1) insert the analyte specific sensor chip in the read-out unit
  2) fill the sample container (sample volume needed for slope determination < 200 µL)
  3) start the measurement process (chip moves into read-out unit and the outlet is punctured (closed previously to prevent uncontrolled intake by capillary forces) and the constant metering pump forces the sample through the measuring channel.

The low-cost chip manufactured in mass-produced plastic injection molding can also contain several functional layers for optimum sample treatment:

- adjustment of pH and/or ionic strength
- filtration of sample (with or without analyte coating)
- separation of cellular blood
- components
- release of further immuno reagents or hydrodynamic puffers.

Figure 84. Optical set-up and construction of the IOS-chip. The laser light from a low-cost laser diode is directed towards the lower plastic baseplate of the immuno-probe chip. The evanescent field is produced within the flow channel produced by the spacer and the cover with sample entrance and outlet holes. The fluorescence of labeled molecules bound to the surface of the baseplate is collected, after passing an interference filter corresponding to the fluorescence wavelength, by a low-cost detector.

The Figure 84 shows the IOS chip design and Figure 85 the simple optical set-up. In Figure 86 a typical calibration plot for the quantification of the important pregnancy hormone hCG is presented. Note: This calibration curve was obtained by using single-use sensors at the corresponding concentration. The error brackets show the standard deviation obtained in each case with five different IOS sensors from one production batch!

Figure 85. Simplicity of the whole measuring process. In the sample container (small dwell) all necessary reagents are present. After sample injection the reagents (with appropriate antibodies) dissolve in the sample and after a variable incubation for the immunological reaction the IOS-chip is automatically transported into the readout instrument where the outlet is punctured and a pump starts to suck the sample through the narrow measuring channel.

What is evident from that calibration curve is its extremely high dynamic range, not typical in the ELISA techniques! The reproducibility can be brought well below 5 % relative, which is outstanding in the trace analytical range. The matrix effect between an aqueous buffer solution and urine can be about 10 % (less) and between buffer and serum about 20 % (less) relative. Both can be compensated for with sufficient accuracy.

Outlook for the IOS technology-DNA-Chip. The IOS technology developed at the ICB Muenster is a base technology with high market orientation, with only as much sophisticated high-tech as needed, optimized for ease of production and quality control, increased production units by generic approach (one base chip for antibody capturing can be used for a wide number of different analytes depending only on the sample container at the inlet). All these advantages can even be topped by the fact that with another optical system delivering a focussed image of sensing spots onto a CCD camera, multi-analyte detection is feasible! Even further, fluorescence-based hybridization events are also sensed with the multi-analyte IOS technology. The upper limit is only given by patent violation reasons and lies at 400 detection spots. This applica-

tion can further trigger mass-production and has the great advantage compared with other DNA-arrays that it quantifies automatically in real time!

Figure 86. Calibration curve for the pregnancy hormone hCG. Each measurement was made with a new IOS sensor. The change of the fluorescence signal is plotted vs. the concentration.

3.4. Whole-Cell Biosensors

Biological cells can be regarded as small membrane-bound structures containing a high concentration of chemicals, including enzymes, nucleic acids, ions, many types of protein, small organic molecules, and a host of others. A major challenge in exploiting whole (intact) cells in biosensor research is the problem of achieving selective transduction of a specific biochemical event or process within the context of this complex cellular chemistry [357], [370], [373], [374], [386] (Fig. 87).

The sensitivity and specificity of a particular cell with respect to a particular chemical varies enormously depending on the type, source, and environment of the cell and the precise nature of the chemical itself. It is not possible to provide any universal guidelines beyond such generalizations as the observation that most mammalian cells respond to a range of highly toxic chemicals, including cyanides. Even in this case it is known that hydrogen cyanide can interact with a number of different cellular components (such as electron transport proteins and enzymes) because of its small molecular size (which facilitates diffusion through biological membranes) and the ability of the cyanide anion to bind strongly to a wide variety of biomolecules.

The stability of biological cells is of critical importance in biosensor applications. In general, cells derived from higher organisms are rather difficult to isolate and maintain in a viable form for the extended periods of time required in most sensor formulations. The most biologically robust cells are derived from less complex organisms, particularly yeast, bacteria, and algae. Cells from these organisms can generally be stabilized in an in vitro environment more easily than complex cells; indeed, many of the organisms themselves are unicellular (yeast, bacteria, algae), leading to biosensors incorporating truly "living" biological components.

Natural cell differentiation and the growth characteristics of such whole-cell biosensors sometimes cause problems associated with signal drift over time. Nevertheless, there are potential advantages to be gained by exploiting whole cells in a sensor format, including:

1) Versatility (cells respond to a wide range of chemicals)
2) The presence in situ of biological structures supporting multicomponent or multistep biological reaction sequences useful for detection purposes and ensuring optimum enzyme activity (many enzymes lose activity when isolated in vitro)
3) Low preparation cost; i.e., growth in culture

For the reasons outlined above, nearly all whole-cell biosensors reported to date have employed relatively simple bacterial or algal cells [372], [387–390]. Existing whole-cell biosensor technology has also been based exclusively on electrochemical transduction of cellular responses.

The increasing interest in whole-cell biosensors since the first reports by Divies [387] and by Rechnnitz [388] has led to the development of a large number of analyte-specific amperometric and potentiometric sensors. In these devices an immoblized layer of whole cells (entrapped in a gel, for example, or membrane-supported) is placed at the surface of an electrode. The cells then function as an enzyme source, where the enzyme of interest is present at a high relative concentration and is effectively able to function in its natural optimized environment. Bacterial cells in particular may contain very large amounts of particular enzymes relative to all others, espe-

Figure 87. Microorganisms as receptor systems in biosensors useful for detecting specific groups of compounds

cially if they are grown on a single source of carbon or nitrogen.

Karube [389] has pioneered in the development of many bacterial electrodes based on this principle using various bacteria depending on the target analyte. Ion-selective electrodes for NH_3, O_2, CO_2, H_2S and H^+ have all been used in conjunction with immobilized whole cells. Riedel et al. [390] have demonstrated that preincubation of certain bacterial electrodes with the desired analyte (substrate) can enhance the sensitivity of a sensor toward that chemical by a factor of as much as 25. This induction approach may prove to be widely applicable. The shelf-life of a whole-cell electrochemical sensor can extend up to several weeks with fully optimized storage conditions (low temperature, for example). Microbe thermistors (sensors that respond to the heat evolved during bacterial metabolism of a substrate) have also been developed, but these present problems once again with respect to analyte specificity.

A significant advance in whole-cell biosensor technology accompanied the development by Rawson et al. [372] of a mediated electrochemical sensor employing a layer of blue-green algae (cyanobacteria). These authors demonstrated that a low molecular mass redox-active mediator, such as $Fe(CN)_6^{3-}$ or benzoquinone, could accept electrons from the photosynthetic energy chain of a cyanobacterium and relay them, via diffusion, to an electrode. The sensor proved capable of detecting aqueous herbicides on the basis of their inhibition of electron transport in the cells. This resulted in a dramatic fall in current, since fewer electrons reached the mediator and hence the electrode. The advantage of this approach to the use of whole cells is that it permits reasonably specific detection of a group of chemicals (herbicides, in this case) rather than limited-range detection of a single substance.

The principal application at the present time for cell sensors is in the measurement of biochemical oxygen demand (BOD) in wastewater. For this purpose yeast and/or bacterial cells (mainly the yeasts *Trichosporon* sp. or *Issatchenkia* and the bacterium *Rhodococcus erythropolis* [370], [386]) are immobilized on top of a Clark oxygen electrode and the oxygen consumption is measured. The great advantage of BOD sensors is a short measurement time (20 s to several minutes) compared with the classical BOD test in wastewater treatment, which requires five days. The main disadvantage is that a BOD sensor reflects only low molecular mass and easily assimilable substrates. High molecular mass substrates such as proteins and starch cannot penetrate the protective dialysis mem-

brane of the sensor. Pretreatment with hydrolytic enzymes could solve this problem. In general, however, BOD sensors, represent a promising approach to the control of wastewater facilities.

Table 21. Potential fields of application for biosensors

Field of application	Biosensor opportunities
Medicine	patient self-control, home health care (glucose, lactate, creatinine, phenylalanine, histamine)
	in vivo analysis
	long-term in vivo control of metabolites and drugs
	control element (biotic sensor) for artifical prosthesis and organs
	rapid analysis at intensive-care units
	surface imaging of organs during implantation
	bedside monitoring
Clinical chemistry	diagnostics for metabolites, drugs, enzymes, vitamins, hormones, allergies, infectious diseases, cancer markers, pregnancy, etc.
	laboratory safety
Environmental protection	pollution control
	monitoring/screening of toxic compounds in water supplies, solid and liquid wastes, soil and air (e.g., pesticides, inorganic ions, explosives, oils, PAHs, PCBs, microorganisms, volatile vapors and gases)
	self control of industrial companies and farms
	alarm systems for signaling hazardous conditions
	determination of organic load (BOD)
Chemical, pharmaceutical, food industry	monitoring and control of fermentation processes and cell cultivation (substrates, metabolites, products)
	food quality control (screening/detection of microbial contaminations; estimation of freshness, shelf life; olfactory qualities and flavor; rancidity; analysis of fats, proteins, carbohydrates in food)
	study of efficiency of drugs
	detection of leakage and hazardous concentrations of liquids and gases in buildings and mine shafts
	indoor air quality checks
	location of oil deposits
Agriculture	quality control of soils
	estimation of degradation/rottage (e.g., of biodegradable waste, or in wood or plant storage)
	rapid determination of quality parameters of milk
Military	detection of chemical and biological warfare agents (e.g., nerve gases, pathogenic bacteria, viruses)

3.5. Problems and Future Prospects

Compared with traditional sensors and classical methods of analysis, biosensors offer an attractive alternative for the rapid, selective, and highly sensitive assay of a wide variety of analytes. Further advantages of this cheap and economical tool emerge with the possibility of direct measurements within complex matrices, demanding only a rudimentary sample pretreatment, and the prospect of an uncomplicated measuring procedure that avoids the use of toxic reagents and organic solvents. Potential fields of application for biosensors are suggested in Table 21.

Until recently, biosensors were available for only a few analytes (roughly two dozen). This is mainly a consequence of insufficient reliability associated with poor stability of the biomaterial, including a dependence on physical and chemical parameters in the environment and interferences within the transducers. In the case of implantable biosensors for in vivo monitoring of metabolites or feedback control of artificial organs (e.g., the pancreas), a lack of biocompatibility with the body environment, organic interferences, and inadequate stability of the biological receptor have so far prevented long-term implantation. Nevertheless, with respect to rapid, sensitive, and selective low- cost determination of a great variety of relevant compounds no suitable alternative to the principle of biosensors is apparent at this time.

Constructing biosensors with greater reliability requires a better understanding of the basic principles of enzyme catalysis and immunochemical reactions, protein structures, pathways for receptor-based signal amplification, and the interfacial behavior of biocompounds at the artificial transducer surface. Biosensor research must therefore be directed toward the following points:

1) Protein engineering, with the aim of enhancing the stability of enzymes, catalytic antibodies, and bifunctional enzymes
2) Screening stable enzymes from microorganisms (extremophiles)
3) Utilization of antibody fragments (Fab, Fab′), bispecific antibodies, and single-chain and single-domain antibodies (tailored through genetic engineering and its expression in bacteria)
4) Recombinant antibodies
5) Modification of the efficiency, specificity, and modulation of antibodies by site-directed mutagenesis
6) Use of DNA libraries for the production of monoclonal antibodies to meet specific demands of the desired transducer

7) Selection and specification of biological receptor systems applicable to the quantification of olfaction and taste
8) Manipulating enzymes and cofactors by electrically wiring redox-active centers to transducer surfaces, utilizing the principles of both molecular electronics and biological electron transfer
9) Investigation of interfacial effects and interactions between biocompounds and transducer surfaces at the molecular and atomic levels by exploiting new methods of surface analysis (e.g., scanning microscopy techniques, fast-atomic-bombardment mass spectrometry, laser-assisted mass spectrometry, time-of-flight secondary ion mass spectrometry, Fourier-transform infrared spectrometry, ellipsometry, X-ray photoelectron spectroscopy, and electron microscopy)
10) Materials research, including biocompatible membranes (based on compounds found within the body) and redox-active electrically conducting (metal)organics and conjugated polymers
11) Development of (multifunctional) silicon-based ultramicroelectrodes covalently linked to biomaterials
12) Preventing the fouling of the biological compounds through microbiological degradation and attacks from proteases

Concerning methodological applications of biosensors, most developments relate to enzyme electrodes integrated into laboratory analyzers for the determination of low molecular mass compounds in the medical and biotechnological fields. A further important line of development is directed toward disposable biosensors for screening and semiquantitative analysis in environmental control, patient home diagnostics, and food-quality control. Direct testing would avoid the time- consuming procedures of sample storage and transfer as well as expensive laboratory analyses. A medium-term application is expected to be the use of biosensors in (quasi)continuously operating random-process analyzers based on micromachined fluidics elements, together with low-maintenance systems for the control and monitoring of water supplies and clinical bedside monitoring. Finally, a long-term target is the development of highly reliable implantable biosensors for long-term implantation. Biosensor applications in the field of instrumentation should also contribute to the solution of many important problems in conventional measuring techniques, opening major new areas to modern analysis.

4. Actuators and Instrumentation

The instrumentation associated with chemical sensors is rather simple and inexpensive, especially in the case of electrochemical transducers and the new IOS technology developed at the ICB Muenster . All that is normally required is a high-ohmic voltmeter (pH meter), a conductometer, and/or polarographic equipment. Fiber-optical devices, on the other hand, can be quite expensive depending on quality requirements with respect to the monochromatic light source. Spectrophotometers with fiber-optical inputs and outputs are already commercially available. A laser source is required in certain cases of sensitive fluorescence measurements with small-volume samples. Exploiting the modern techniques of acoustic wave modulation also requires more than a simple frequency counter. For example, a network analyzer can be of great help in following the shift in a resonance curve caused by interaction of an analyte with the transducer surface.

The highest costs are usually related to development of a selective analyte recognition layer, perhaps the most important part of a complete chemical sensor. Transducer technology is much more highly developed; indeed, there seems to be little need here for further improvement without equivalent improvements in the selectivity of sensor elements.

An important area of sensor research is microsystem technology (mst). A microsystem is defined as one too small to be fabricated by traditional miniaturized mechanical techniques, especially one that is dependent on modern mass-production techniques involving silicon or LIGA technology. A *system* must, by definition, consist of at least two interactive processes. A typical example is the antiblocking brake system (ABS) in an automobile, in which acceleration sensors are capable of detecting a blocked wheel and selectively controlling the brake power to that wheel via actuators.

Examples of analogous complete systems in chemistry are still rare. The best example is perhaps the "artificial pancreas," in which a glucose sensor measures the actual blood-glucose concentrations in order to control an appropriate actuator, the insulin pump. Bedside devices for this purpose have operated successfully for many years, but all attempts at implantation have so far failed, mainly because of the limited lifetime of the glucose biosensor and biofouling of the biosensor membrane by macrophages and other body constituents.

A complete system providing both a sensor and an actuator would be ideal in the field of process control, but because of a lack of truly reliable chemical sensors on the market the concept has not been widely implemented. One exception relates to the analytical method of coulometry, a technique that offers great potential for delivering chemical compounds to a controlled reaction. Especially attractive in this context is the method of constant- current coulometry, which can be carried out with an end-point sensor and a coulometric actuator for maintaining a generator current until the end-point has been reached. In this case both of the required devices can be miniaturized and constructed with the same technology.

5. Future Trends and Outlook

Surveys that have been conducted on the subject of chemical sensors all predict a growing market during the late 1990s and the early years of the 21st century [391–393]. Anticipated developments in automation, environmental protection, health care, and high technology ensure a strong demand for sensors. However, devices of this type must become increasingly reliable, must survive a thorough validation, and become even simpler to use. Japanese researchers see the first area for mass application of sensors to be the health care industry, especially with respect to the elderly. The demographic prospect of an increasing number of retirees and a lack of sufficient care centers may trigger the use of many sensors for monitoring the health of people living for as long as possible in their own homes. It is now clear that the application area of health care will dominate the application of biosensors. The "point of care" idea will replace large central laboratories to which the labile biological sample has to be transported. The reliabilty, built-in validation checks, and ease of use will allow their use by the normal physician who will have then the result within a few minutes. While the numbers of DNA arrays used in the genom research area will become saturated shortly, the use of simple arrays for looking for specific protein expression patterns will increase. Combining bio-informatics with the latter in finding super-marker molecules for extremely early tumor diagnostics will be possible. This leads to the corresponding mass-production of these diagnostic chips.

With respect to environmental chemistry, controls over the emission of organic compounds will undoubtedly be strengthened in the future. For example, municipal incinerators without provisions for the effective measurement of all hazardous organic compounds will soon be strictly forbidden everywhere. It seems likely that a large fraction of the moneys previously spent for defense purposes will be redirected toward improvements in continuous measurement technology. Sensors will be required to compete in this respect with such fast separation methods as capillary electrophoresis or flash chromatography, which permit the separation of most compounds within only a few minutes.

One critical remark is in order regarding papers published in the field of chemical sensors. Many such reports reflect a lack of input from qualified analytical chemists during the development and testing stages. Insufficient understanding is often apparent with respect to the analytical process itself and the difficulties involved in obtaining a truly reliable result; indeed, many sensor researchers seem to be unaware of such basic problems as sample – matrix effects. Anyone who claims to have developed a new sensor should be required to demonstrate its effectiveness with a real sample under real conditions. The latter is required and called validation by international quality standards (ISO 25). Publications that fail to reveal this most important feature of a sensor are also essentially worthless. Chemical sensors are analytical devices, so they should be subject to the same standards of characterization as other instrumental tools. Quality-control considerations mandate critical evaluation of any new molecular sensor presented to the scientific community. Every report concern-

ing a new sensor development should clearly delineate the crucial features, with none omitted.

The most important parameters for characterizing or validating a chemical sensor or a biosensor include:

1) *Selectivity.* The selectivity with respect to important known interferents for the particular application in question should always be expressed numerically; expressions like "relative selectivity" toward the analyte, or "not affected by typical concentrations of interfering compounds" are inappropriate.
2) *Sensitivity and Limit of Detection (LOD).* The slope of a calibration curve expressed in the appropriate units (e.g. microamps, millivolts, or hertz) per millimole or micromole should always be provided both for a matrix-free solution and for a sample in its matrix. The corresponding LOD should also be reported in both cases. In the absence of a blank the signal 3 × larger than the noise determines the LOD. The limit of quantification is typical 10 × LOD.
3) *Stability of the Analytical Function (Drift).* A zero-point drift value should be provided for a sensor in a matrix-free solution and also with respect to real samples involving a matrix. The same applies to the stability of the slope (varying sensor sensitivity).
4) *Response Time.* Since response time is also a function of the sample matrix it should be measured both in pure calibration solutions and with real samples. Generally two different response times are observed, one for a concentration rise and one for decreasing analyte concentration, with the latter usually slightly greater. Since IUPAC has not yet recommended a specific procedure for measuring this parameter, one should express the response time in the form of a time constant (=1/e of the final value), since this is the approach taken with electronic circuits. Only in the case of a sensor that never reaches its final value should other approaches be considered for characterizing the rate of response to a changing analyte concentration.
5) *Sensor Lifetime.* Especially in the field of biosensors the lifetime of a sensor in contact with a calibration solution or a real sample, or during storage in a refrigerator with an optimal conditioning solution, is of considerable interest, and it should always be mentioned. Conditions leading to rapid sensor fouling should also be identified in order to permit appropriate precautions to be taken. Examples include the fouling of certain enzymes by inhibitors or heavy metals, or microbiological attack. Any use of conditioning solutions containing metal complexation reagents, inhibitor scavengers, sodium azide, etc., should be clearly described.

Other important information might include total power consumption, auxiliary equipment costs, total elapsed time between failures, temperature compensation measures, or maintenance requirements.

Finally, sensor developers must remain aware of progress within instrumental analytical chemistry generally, especially in the area of fast high-resolution chromatography. Indeed, progress has already been so great in the latter field that more than 20 anions (including phosphate) can now be separated completely in less time than would be required for a response from a multienzyme phosphate biosensor! The serious challenge this poses to sensor advocates will be obvious.

1. Modern Optical Microscopy

Andres Kriete, Heinz Gundlach, Severin Amelinckx

1.1. Introduction

Optical microscopy goes back as far as the 16th century, when magnifying glasses and optical lenses became available. ANTONI VAN LEEUWENHOEK (1623 – 1723) observed structures lying beyond the resolution limit of the eye, such as bacteria, with a 270-fold magnifying, single lens. The exact design of the microscope was established from a theory of image formation developed by ABBE in 1873 [1]. With the introduction of apochromatic lenses (⟶ Optical Materials – Effect of Partial Dispersion on Optical Imaging) and oil immersion, a theoretical resolution limit of 0.2 µm became available at this early stage. Light microscopy advanced further by new lens designs, optical contrast enhancement methods, and application of fluorescent and immunofluorescent dyes, also in combination with inverted microscope designs. Optoelectronic methods, such as video techniques, have further broadened the spectrum of light microscopic applications. Finally, laser scanning techniques and confocal imaging allowed the investigation of microscopic structures three-dimensionally. Compared with a standard microscope, the confocal microscope has enhanced lateral and axial resolution, as well as it has improved contrast, and in particular it can remove out-of-focus blur. Thus, an optical, noninvasive sectioning capability is achieved. The breakthrough of confocal microscopy in biomedicine and material science boosted the development of a variety of commercial confocal laser scanning microscopes. Highly developed optoelectronic components such as laser light sources and sensitive detectors, as well as the application of specific fluorescent dyes, enabled wide acceptance of this new imaging technique together with effective use of powerful computers to digitally store, visualize, and analyze three-dimensional data. The combination of these developments has also led to high-throughput applications of modern light microscopy for drug development.

1.2. Basic Principles of Light Microscopy

1.2.1. *Optical Ray Path*

The rigid *stand* of the microscope is the “carrying” element, with mechanical and optical parts attached. The *objective* is the central optical unit, generating an intermediate image that is magnified by the *eyepiece* for visual observation [2-4]. *Condenser* and *collector* optimize specimen illumination. Lens designs corrected for a *finite length* form a mirrored, magnified, aerial (intermediate) image, which is projected infinity by the eyepiece (Fig. 1). The distance between the back focal plane of the objective and the primary image plane (which is the front focal plane of the eyepiece) is defined as the *optical tube length*. The *mechanical tube length*, measured from the mounting plane of the objective to the mounting plane of the eyepiece, is 160 mm for currently used microscopes. Any aberrations present in the intermediate image, such as the lateral chromatic aberration (LCA), are compensated by the eyepiece. Optical – mechanical components such as the Bertrand lens, or epi-illuminating reflectors mounted within the optical path require a so-called telan system. Objectives of *infinity-corrected designs* generate an infinite image projected into a real image by the tube lens (Fig. 2). The infinity color-corrected system (ICS) optic is an example of how the tube lens together with the objective can correct aberrations, particularly chromatic ones [5]. The intermediate image is monochromatic; consequently, photographic and video recording do not require compensating lenses. Moreover, the path between lens and tube lens may be used by all optical – mechanical components for various illuminating and contrast generating methods without telan optics (Fig. 2).

1.2.2. *Imaging Performance and Resolution*

The image generation in microscopy cannot be explained sufficiently by means of geometric optics alone; wave optics

must also be considered [1, 6]. Imaging a point source generates a diffraction pattern in the focal plane. The central parts of this Airy disk contain most of the intensity; therefore, the diameter of this kernel can be defined as the smallest resolvable image element (Fig. 3 A – D). The diameter of the kernel d_k is given by

$$d_k = 1.22\lambda / n \cdot \sin \alpha \tag{1.1}$$

with λ being the wavelength, *n* the refractive index of the material, α the angle between the optical axis and the marginal beam of the light cone that enters the objective, and $n \cdot \sin \alpha$ the numerical aperture (*NA*).

Figure 3. A) and B) Intensity distributions in the image of a luminous point; C) Computed intensity distribution; D) Airy disk

a) Image plane; b) Lens; c) Objects plane

The resolution limit for two points is reached when the maximum of the first diffraction spot coincides with the first minimum of the second one. ABBE developed this theory and proved it experimentally in his historical papers [1]. The resolution is calculated from the available numerical aperture and the wavelength λ by

$$d_r = 1.22\lambda / NA_{obj} + NA_{cond} \tag{1.2}$$

As an example, a lens and condenser of *NA* = 1.4 and λ = 530 nm give a smallest separation of *d* = 200 nm. Resolution can be improved either by a higher *NA*, which is difficult to obtain in lens design, or by using shorter wavelength, as in ultraviolet microscopy [7].

Both the size of the diffraction spot and the resolution of the eye define the utilizable magnification. Since the resolution of the eye is ca. 2 – 4 arcminutes, total magnification should not exceed 500 – 1000 times the numerical aperture. Magnification above this limit does not deliver any additional information, but may be used for automatic measuring procedures or counting.

1.2.3. *Characteristics and Classification of Lenses*

The imperfections of optical lenses give rise to various distortions, either monochromatic or chromatic, (see also ⟶ Optical Materials – Effect of Optical Material on Imaging) that are visible in the diffraction pattern. Monochromatic distortions include aberration, curvature, astigmatism, and coma. Chromatic aberrations are caused by differences in the refractive index of glasses. These types of errors are minimized by combining several pieces of glass with different form and refractive index, or by using diaphragms. The three main categories of lenses are

1. Achromatic objectives
2. Fluorite or semiapochromatic objectives
3. Apochromatic objectives

Fluorite and apochromatic lenses are mostly designed as plane (i.e., corrected for a flat field of view). Computers allow calculation of the diffraction pattern under various imaging conditions to optimize imaging performance for a wide range of applications. The present advantage in modern lens design and production is indicated by the image quality of the ICS Plan Neofluar class. At a field-of-view number of 25, color photography, as well as all optical contrast enhancement methods, are supported with achromatic correction comparable to apochromatic lenses with a good transmission down to UV at 340 nm. These objectives are generally applicable for all fluorescent methods (see Sections Fluorescence Microscopy, Imaging Modalities and Biomedical Applications). Plan apochromates feature a still higher aperture: chromatic rendition is improved, as well as correction at the field-of-view boundary; therefore these objectives are very suitable for color microphotography. In addition, a complete correction not only at the focus level but also for a limited range above and below the focal plane is achieved. For specific applications, the following lenses are also available:

1. Multi-immersion objectives of type Plan Neofluar, corrected for use with oil, glycerol, or water, with or without a cover glass
2. Objectives for specimen without cover slide
3. Objectives with a long working distance
4. Objectives with iris diaphragm
5. Objectives for phase contrast investigation
6. Objectives, strain free for polarized light microscopy
7. Ultrafluars, corrected between 230 and 700 nm

1.2.4. *Eyepieces and Condensers*

The main characteristics of *eyepieces* are magnification and type of correction, such as color compensation and correction of viewing angle. The correction of the *condensers* must match the properties of the lenses. Special or combined condensers are required for certain methods of contrast generation or for longer working distance with inverted microscopes.

1.3. Illumination and Contrast Generation

Illumination and contrast are central points in the discussion of imaging performance. Without sufficient contrast, neither the required magnification nor a maximal resolution can be obtained. A. KÖHLER developed optical illumination for microscopy in 1893 [8]. The main advantage of Köhler illumination is that in spite of the small filament of the light bulb, the entire area of the lamp field stop, as well as the illuminated part of the specimen, have a uniform luminance (Fig. 4). The twofold ray path of diaphragms and lenses suggests that adjustment of the condenser iris, being the illumination aperture, controls resolution, contrast, and resolution depth. This principle is also important for correct setup of the confocal microscope as well as electron microscopy.

Figure 4. Schematic of Köhler illumination

1.3.1. *Optical Contrast Generation*

For the following considerations the principles of wave optics are used, which describe image formation as a result of diffraction and interference.

Dark-Field Illumination. In dark-field illumination the illuminating aperture is always set higher than the lens aperture. Only light waves being diffracted by the microstructures are captured by the lens. Objects appear as bright diffraction patterns on a dark background.

Phase Contrast. Based on ABBE's theory the Dutch physicist FRITS ZERNIKE (Nobel prize in 1953) developed phase contrast imaging in 1935, to convert the invisible phase shift within the specimen into recognizable contrast [9]. A phase plate located in the lens modifies the phase and amplitude of the direct (illuminating) wave in such a way that a phase shift of $\lambda/2$ is obtained (Fig. 5). The amplitudes of the direct diffracted waves are equalized, and by destructive interference, dark-phase objects appear on a bright background. The application of this technique ranges from routine diagnosis to cell biology research [6, 10]. Today this method is also used advantageously in combination with epifluorescence. The specimen is adjusted under phase contrast before switching to fluorescence light in order to avoid bleaching, or both imaging modes are combined to match the fluorescent signal with the morphological image.

Figure 5. Image path of the phase contrast microscope, converting phase shifts into a noticeable contrast

a) Illuminating diaphragm ring; b) Condenser; c) Specimen generating a phase shift; d) Objective plate; e) Phase plate; f) Intermediate image

Nomarski Differential Interference Contrast (DIC). In 1955 the physicist GEORGE NOMARSKI simplified the two-beam interference microscope in a way that it became available for routine microscopy [11] (Fig. 6). DIC uses modified Wollaston prisms (Fig. 6 B), lying outside the focal areas of condenser and objective [11-13]. Normal lenses are used; the contrast can be adjusted by shifting the lens-sided prisms. As in phase contrast, differences in the optical path length are visualized. Objects appear as a relief, and thick specimens lack the halo-typical pattern of phase contrast imaging. Full aperture of both the objective and the condenser allow optical sectioning (Fig. 7). Combined with inverted microscopes (see Section Inverted Microscopy) and contrast-enhanced video microscopy (see Section Optoelectronic Imaging), ultrastructures in cells and tissues can be imaged. Certain applications combine DIC with phase contrast. For routine applications, phase contrast lenses may give better results at lower magnification. The DIC image is well suited to be combined with a fluorescent image as well.

Figure 6. A) Image path of a two-beam interference microscope; B) Nomarski prism with direction of optical axes and position of interference plane indicated

Contrast is generated by a phase shift of the polarized and prism-split illuminating beams, which are combined by the second prism

Figure 7. A) – C) Optical sectioning of salivary gland of drosophila by DIC Nomarski (Specimen courtesy of L. Rensing, Universität Bremen, Germany)

Polarization and Reflection Contrast Microscopy. Polarization microscopy is used preferentially for certain applications in cell research, to enhance double diffraction (anisotropic) structures such as muscle fibers or the mitotic apparatus. Quantitative studies require strain-free polarization lenses for the polarized light used. With the help of reflection contrast microscopy [14, 15], visible interference is generated at epi-illumination, for example, to study adhesive properties of living cells on glass surfaces [16]. Moreover, this method may be combined with phase contrast or Nomarski DIC contrast. For the evaluation of immunogoldmarked specimens, immunogold staining (IGS), reflection as well as transmission contrast is feasible.

1.3.2. *Fluorescence Microscopy*

Basic Principles. The development of immunofluorescence greatly influenced medical practice and basic biomedical research [17-20]. Many biomedical specimens emit *autofluorescence* if illuminated properly. Today a wide range of fluorescent microstructures can be excited by application of fluorochromes (*secondary fluorescence*). Immunofluorescence is based on antigen – antibody connectivity [21]. This couples the high specificity of the immune reaction with the extreme sensitivity of fluorescence microscopy. Various markers for antibodies exist and derivates of fluorescein, mainly fluorescein – isothiocyanate (FITC), are the preferred fluorochromes. For this kind of microscopy, special lamps and filters are required. Light sources used include high-pressure bulbs as well as lasers. Fluorescence microscopy is used either in transmission or in epi-illumination; the latter combines phase contrast and Nomarski DIC [22, 23]. Fluorescence microscopic objectives with high aperture and a good transmission between 340 and 700 nm are preferred. Multi-immersion lenses of plan-type Neofluar have been designed specifically for such applications, as well as low-magnification lenses featuring high apertures (primary magnification 40, *NA* 1.3 oil). Plan apochromates are more suitable for illumination in visible light. The brightness *b* of fluorescent images increases proportionally to the square of the numerical aperture of lens L and condenser C, and decreases inversely with the square of the total magnification *M*

$$b \sim \frac{NA_L^2 + NA_C^2}{M^2} \tag{1.3}$$

This makes ocular lenses with low primary magnification an ideal choice. At epi-illumination the brightness depends on the power of four of the aperture, since the lens acts as the condenser as well:

$$b \sim \frac{NA_L^4}{M^2} \tag{1.4}$$

In the 1980s, fluorescence methods became a major tool for sensitive and highly specific detection in biomedical research and medical diagnosis.

Fluorescent Dyes and Markers. The development of reagents based on fluorescence includes the use of biological molecules: antibodies, RNA, DNA, proteins, and other macromolecules and physiologic indicators [17-19]. These methods have enabled new findings in cell biology, molecular biology, developmental biology, and cancer research. The cytoskeleton (Fig. 8) is responsible for the cell shape, cell division, capacity of the cell to move, and the intracellular transport of cell organelles [24, 25]. Multiparameter fluorescence microscopy uses a broad selection of fluorescent dye molecules to examine several properties or components of a single cell simultaneously (Fig. 9).

(Courtesy of L. TAYLOR, University of Pittsburgh, United States)

A series of new probes suitable for this purpose has been developed by extending the usable spectrum to the near

infrared (Fig. 10). *Fluorescence-based in situ hybridization* (FISH) is rapidly being recognized as a powerful tool for detecting and quantifying genetic sequences in cells and isolated chromosomes [26]. FISH is based on the highly specific binding of pieces of DNA, labeled with a fluorescent probe, to unique sequences of DNA or RNA in interphase nucleus or metaphase chromosomes. Recent developments enable the simultaneous visualization of three or more DNA regions (chromosome painting) [27].

Figure 10. A) Micrograph by triple exposure of color slide film using conventional fluorescence microscopy; B) Pseudocolored digital image recorded with the CCD camera for chromosome 1, 2, 7, 8, 9, 12 and the human X chromosome

(Courtesy of T. CREMER, Heidelberg, Germany and Oxford University Press)

Comprehensive reviews of available fluorochromes have been published elsewhere [28-31]. UV lasers broaden the spectrum of applicable fluorescence dyes. The green fluorescence protein (GFP) is a strongly fluorescent reporter molecule that stems from the jellyfish *Aquorea victoria* [32]. It has a fluorescein-like characteristic, it requires no cofactors or substrates, and is species-independent. GFP engineering has produced different color mutants which have been used for gene expression, tracing of cell lineage, and as fusion tags to monitor protein localization [33].

Fluorescent semiconductor nanoparticles (quantum dots, Q-dots) have the benefit of bright fluorescence without any photobleaching, thus allowing for extended-time observation of a biological system [34]. Simultaneous tracking of Q-dots of different colors Q-dots is possible due to their broad absorption and narrow emission spectrum [35]. They are excited by wavelengths below 480 nm, and emit at various wavelengths from 490 to 700 nm with sharp, well-defined absorption spectra [36]. Full width at half maximum intensity ranges from 20 to 40 nm. Different types of coating chemistries have been employed to render the Q-dots hydrophilic and suitable for further conjugation with antigens and antibodies of interest (see Fig. 19) [37].

Time-Resolved Methods. Special methods and dyes have been developed to observe functional phenomena in living cells. Fluorescence lifetime imaging microscopy (FLIM) monitors fluorescence lifetime as a function of environmental parameters of cellular components. These include Ca^{2+}/pH-sensitive indicators, also called biosensors [19]. Typically a fluorescent dye is chemically linked to a macromolecule, creating an analogue of the natural molecule. The fluorescent analogue is specifically designed to measure chemical properties of the macromolecule, instead of tracking its location within the cell. Time-gated multichannel plates (MCPs) are used for time- and spatially resolved measurements.

Fluorescence recovery after photobleaching (FRAP) and the measurement of the fluorescence resonance energy (FRET), which allow the diffusional mobility of cellular components and their interaction at the molecular level to be monitored are other varieties of time-resolved methods [38, 39]. A novel method is fluorescence correlation spectroscopy (FCS), which measures the statistical fluctuations of fluorescence intensity within a confocally illuminated volume. Correlation analysis allows the concentration of particles and their diffusion to be determined [40, 41]. FCS has proved be useful in the study of enzyme kinetics, DNA/protein interactions, receptor/ligand interactions, and cellular measurements [42]. Molecular interactions can be studied without interfering with the natural binding conditions, since only the reference substances in competition experiments need to be fluorescently labeled.

1.4. Inverted Microscopy

Inverted microscopes were originally designed for the evaluation and counting of plankton and sediments [43]. The first inverted research microscope which included photomicrography, microphotometry, cinemicrography, and video imaging was the Axiomat [4, 44-46]. Inverted microscopes in U-design (Fig. 11) with a rigid stage are of great advantage for investigations in cell and developmental biology, as well as in cell physiology experiments that are performed in optical microscopes [47-49]. Identification and selective micropreparation on live nuclear components in oocytes of *Xenopus* in the DIC Nomarski technique facilitate high-resolution optical microscopy in different planes of the specimen (optical sectioning), which can be isolated by selective micropreparation for subsequent analysis in the electron microscope [50].

Figure 11. Light path of an inverted microscope

In the life cycle of the green alga *Acetabularia*, high-resolution phase and DIC microscopy have made part of the endoplasmic reticulum and lampbrush chromosomes visible [51]. The distinct advantage of inverted compared to upright microscopes is the unhindered application of cell and tissue culture chambers in conjunction with micromanipulators, micropipettes, microelectrodes (patch clamp method), and injection systems for experimental cell research. Computer-controlled microinjection can be performed automatically [52]. Manipulation of cells, organelles, and genomes is also possible by means of laser microbeam tweezing and optical trapping [53].

1.5. Optoelectronic Imaging

Electronic imaging methods such as video microscopy and laser scanning microscopy can extend resolution slightly, but the ability to extend the detectability of subresolved structures and subresolution movements is more important. A video camera can generally be mounted to the same port employed for normal photomicrography. In *video-enhanced contrast microscopy* (VEC) (Fig. 12), high-resolution video cameras based on a vidicon tube are used. This principle of adjusting gain, and offset and digital image processing is also used in laser scanning microscopes (see Section Confocal Laser Scanning Microscopy). Digital imaging and image processing make it possible to see structures that are smaller than the resolution limit [12, 54-57]. By means of this method, single microtubules can be observed [58, 59]. The size of each microtubule is only one-tenth of the visible-light resolution limit. In the 1980s, solid-state cameras were introduced into microscopy [60, 61]. Most of them are based on a *charge coupled device* (CCD), which produces digital data directly for computer processing and image analysis. For low light level (LLL) or video intensification microscopy (VIM), i.e., weak fluorescence or small FISH signals (see Fig. 10 B), cooled, sensitive CCD cameras for black and white or color are available now and have replaced tube cameras [62]. Digital imaging techniques have gained increasing attention as supplements to conventional epifluorescence and photomicrography [63]. *Microphotometry* permits spectrophotometric analysis of substances, as well as statistical and kinetic measurement and compilation of two-dimensional intensity profiles [49].

1.6. Confocal Laser Scanning Microscopy

1.6.1. *Basic Principles*

The fundamentals of confocal microscopy go back to 1959, when MINSKY described a new kind of microscopic apparatus [64]. The historical development of confocal microscopy is reviewed elsewhere [65, 66]. Two different kinds of confocal instruments are available: the tandem scanning microscope and the laser scanning microscope. The *tandem scanning microscope* uses normal light chopped by a rotating Nipkow disk [67]. The light beams reflected by the specimen cross the rotating disk on its opposite side (thus tandem), and due to the symmetric pattern of holes, out-of-focus blur is removed. This system allows real-time and real- color imaging, but is limited in sensitivity because of the fixed size of the pinholes.

The more commonly applied *confocal laser scanning microscope* (CLSM) features a variable pinhole and allows adjustment of magnification by modifying scan angles. A schematic example of the principle of confocal laser scanning is given in Figure 13. The laser light is focused via the scanner (b) through the tube lens (c) and the objective (d), and illuminates a small spot in the specimen (e). Emitted light emanating from the focal plane and the planes above and below (dotted and dashed lines) is directed via the scanner to the dichroic beam splitter (a) where it is decoupled and directed onto a photomultiplier (i). A pinhole (h) in front of the photomultiplier is positioned at the crossover of the light beams emerging from the focal point. This plane corresponds to the intermediate image of the Köhler illumination described in Section Illumination and Contrast Generation. Light emanating from above and below the focal point has its crossover behind and before the pinhole plane so that the pinhole acts as a spatial filter. Numerous papers elucidate the basic aspects of confocal image formation and application [68-72], including a handbook [73].

Figure 13. Ray path in the confocal microscope

a) Dichroic beam splitter; b) Scanner; c) Tube lens; d) Objective; e) Specimen; f) Focal plane; g) Filter; h) Pinhole; i) Detection system (photomultiplier)

Since only a small specimen point is recorded, the entire image of a specimen is generated by either moving the specimen (*stage scanning*) or moving the beam of light across the stationary specimen (*beam scanning*). The latter is utilized in all commercial instruments (Fig. 14). Theoretical considerations have shown that both scanning forms give identical resolution. The optical sectioning capability at lateral scanning opens a way to image a three-dimensional structure with a slight axial stepping of the stage (see Fig. 15).

Figure 14. Setup of the confocal microscope, based on a research light microscope (Zeiss)

1.6.2. *Imaging Performance*

The imaging characteristic in confocal microscopy is given by the properties of the specimen weighted by the applicable spatial confocal response function. An explanation based on wave optics suggests that the point spread functions of the illuminating path and the detection path (resembling the photon detection possibility) are convolved, consequently resulting in a narrow point resolution [74].

Describing image formation of an reflecting object and the corresponding coherent imaging properties must be distinguished from a fluorescent object viewed in incoherent imaging because in the latter the illuminating wavelength and the detected wavelength are different. In terms of resolution, the Rayleigh criterion determines the minimum resolvable distance between two points of equal brightness (see Eq. 1.2). For *incoherent imaging* using a lens with a certain numerical aperture *NA* at a wavelength λ, the *lateral resolution* d_r obtainable in confocal imaging is [71]:

$$d_r\,(\text{conf.}) = 0.46\lambda/NA \tag{1.5}$$

With a wavelength of 514 nm (green argon laser line) and a numerical aperture of 1.4, this equation gives a resolution of d_r = 157 nm. Compared to conventional imaging (see Eq. 1.2), the resolution is ca. 32 % higher [75].

An approximation of the *axial resolution* d_z is given by

$$d_z\,(\text{conf.}) = 1.4\lambda/NA^2 \tag{1.6}$$

The values (514 nm and *NA* = 1.4) give a d_z of 367 nm.

One way to measure the axial response of a confocal microscope is to record light intensity from a thin layer with infinite lateral extension. In a conventional microscope, no difference — and therefore no depth discrimination — are obtained. However, in confocal microscopy, a strong falloff occurs if the object is out of focus. The free width at half maximum (FWHM) of such a function is proportional to the optical section thickness [73, 76]. The optical section thickness also depends on the diameter of the pinhole. The optimum pinhole size *D* with a maximum deterioration of 10 % in reflection is given by [72]

$$D = 0.95\lambda M/NA \tag{1.7}$$

with magnification *M*, λ, and *D* given in micrometers. In fluorescence microscopy the size has to be reduced 10 – 30 %, depending on the ratio of excitation to emission wavelengths. Another way to describe the imaging performance is by the modulation transfer function (MTF) (see also ⟶ Photography – Modulation Transfer Function.); such measured and theoretically derived three-dimensional functions have been published [77, 78].

1.6.3. *Instrumentation*

Confocal microscopic equipment is available as an add-on to a standard microscope or in the form of more fully integrated devices, including computer control equipment. Both upright and inverted types of microscopes are available. The inverted confocal microscope allows bigger specimens to be studied and offers easy handling of micromanipulating or injecting devices (see also Section Inverted Microscopy). Beam scanning is obtained by rotating galvanometric mirrors. Axial control is realized by a stepping motor drive or a piezoelectric translator. Most instruments are equipped with several detectors to record multifluorescence events simultaneously. Some also offer transmission detectors. Signals from different channels can then be mixed electronically (see Fig. 16). Confocal transmission microscopy has also been studied. Improvement of contrast and resolution depending on the pinhole size of a thin specimen has been documented in a confocal transmission arrangement using differential interference contrast [79].

Figure 16. Multichannel confocal image of macrophages (J774, mouse cell line)

Extrathyroidal release of thyroid hormones from thyroglobulin is marked by fluorescence dye (first channel, green); actin cytoskeleton is labeled with rhodamine-phallodin (second channel, red). Morphological information (third channel), providing a dark background in the cells, is detected in transmission.

(Permission of K. BRIX, V. HERZOG, Institut für Zellbiologie, Bonn, Germany)

Variations of the confocal design have been developed, such as bilateral scanning in real time with a scanning slit [80]. Because of the fast scanning, TV detectors such as a sensitive CCD camera are best suited. Slit-scan confocal microscopes offer a better signal-to-noise ratio and real-time imaging capabilities but a slightly reduced resolution

compared to a conventional CLSM.

Various types of lasers can be linked to the microscope [81], but up to now only continous-wave gas lasers have been used routinely. This includes argon-ion lasers having excitation lines at 488 and 514 nm and helium – neon lasers with a major line at 633 nm and a weaker line at 543 nm. The use of UV lasers requires achromatic lenses and specifically designed scanning mirrors. Lasers used in the UV range are argon-ion UV or argon-ion tunable lasers, as well as krypton-ion and helium – cadmium lasers. Depending on the emission lines of the fluorescent dyes, various filters are used in front of the photomultiplier, characterized by quantum efficiency and spectral response. The total sensitivity of a system is given by the transfer efficiency of the various optical components [82] and, in addition, the quantum efficiency of the detector and its associated electronics [83].

Simplified types of laser scanning microscopes, such as the *fiber scanning optical microscope* have also been proposed [77]. Here the fiber can act both as a light delivering source and as a pinhole. A totally different physical approach to reduce out-of-focus blur is based on a physical phenomenon called *double-photon (2 p) excitation*, whereby fluorescence is generated by simultaneous absorption of two photons of long wavelength at a single molecule. The necessary energy emitted by pulse lasers is present only at the focal plane; thus a “confocal” effect is produced. At turbid tissue media, the signal level under 2 p-excitation drops much faster than that under single-photon excitation, although image resolution is higher in the former case [84, 85].

The diffraction pattern of the illuminating beam is elongated axially compared to the lateral direction (see Eq. 1.5 versus 1.6). This anisotropy is caused basically by the limited numerical aperture of the microscopic lens. An optimal diffraction pattern would be achieved by an unlimited, 360° aperture. This concept is known as the *4-pi microscope*. Prototypes use two facing lenses or two lenses oriented at an angle (theta microscopy). The object in focus is illuminated from two sides, and fluorescence emanating from the object is detected through both lenses [86]. Such concepts have been recognized as entry-points for fluorescence nanoscopy [87].

Special techniques for 3D imaging of particular thick specimen several microns in depth have also been suggested, including optical coherence tomography [88] and selective plane illumination microscopy [89].

1.6.4. *Imaging Modalities and Biomedical Applications*

Imaging Modalities. Confocal contrast generation include reflectance, rescattering, and fluorescence. The first results in confocal imaging were obtained on unstained tissue in *reflectance* [90]. Reflectance is also the preferred imaging modality used in industrial inspection of semiconductors, often combined with methods such as optical beam induced conductivity (OBIC).

In biomedical science, the study of unstained tissue is limited due to reflectance. The reflectance must be intensified by metal impregnation (e.g., Golgi stain); one such example is given in Figure 17. Other examples include peroxidase – labeling with nickel intensification in neurobiology [91] or silver-stained nucleolar organizer region-associated proteins (AgNORs). Gold immunolabeling has also been used [92]. In *rescattering*, variations in the refractive index can give rise to reasonable contrast. One particular example is in ophthalmology [93] where structures in the transparent cornea such as cell nuclei, keratocytes, neurons, or the fibers of the lens can be visualized (see Fig. 18).

Fluorescence is the most commonly used imaging mode in confocal microscopy, such as, applications in cell and neurobiology [93-100], which include the use of autofluorescence, specific dyes in combination with antibodies, and in situ hybridization. For specifics on fluorescent dyes and markers see Section Fluorescence Microscopy.

Biomedical Applications. Optical sectioning devices, being noninvasive and having low radiation damage, are ideal for studying living specimen, organs, and tissues. With confocal microscopes, structures can be observed in vivo at full three-dimensional microscopic resolution [94]. Small organisms or organisms in an early stage of development can be observed, as in embryogenesis [97, 98]. Concerning individual structures, kinetics of labeled receptors (see Fig. 19), morphological changes, such as the movement of cell compartments (see Fig. 20), growth of neurons [99], or synaptic plasticity in the retina, have also been studied [100]. Confocal microscopy is also used in clinical imaging, which includes the observation of wound healing, flow processes in veins, and ophthalmology [94, 96] (see Fig. 18).

1.7. Computer Applications in Digital Microscopy

Computer applications in digital microscopy include image storage in databases, compression, enhancement, analysis, and visualization. Digital analysis applied to microscopical data sets has the aim of automatically extracting structures of interest out of digitized images and then quantifying them. This includes field-specific or stereological, geometrical or object-specific, and intensity-related parameters. In the case of 3D images, typically generated by a confocal imaging technique, a computer graphical 3D visualization of the data stack is performed, which allows inspection of the original data and subsequent image-processing operations.

Different digital image formats are used in microscopy, for example, the TIFF format. In 1999, a microscopic imaging standard was established by the ARC-NEMA Institute as part of the DICOM standard (Digital Imaging and Communication in Medicine). This format, DICOM-VL (Visible Light), regulates storage of instrumental and specimen parameters besides the image information. This fosters the use of microscopic images in telemicroscopic applications and in medical networks. The vast amount of data in larger studies, and in particular multidimensional data, has led to the development of new concepts in computing and visualization that utilize special data compression techniques [101], as well as compressions schemes for regulated environments [102].

1.7.1. *Image Analysis*

Image quality assurance is an important control mechanism for image data to be analyzed quantitatively. Appropriate techniques include sampling [103], focus setting techniques [104], image quality measurement [105], and calibration routines [106]. Some of the undesired phenomena which influence or prevent successful application of image analysis require preprocessing. This includes attenuation of the laser beam in thick specimens, photobleaching or saturation of the fluorescence, autofluorescence, and background noise, and the distortions caused by the embedding media [92, 94, 107]. The loss of resolution in thick specimens is shown in Figure 18. The correction of such phenomena is often limited by the underlying theoretical models selected, since the effects are highly object dependent.

Undesired effects in fluorescence confocal microscopy can be corrected by ratio imaging. Ratioing (i.e., the compensation of two channels by digital division) can substantially reduce cross-talk effects in double detectors [72]. Environmental markers indicating the pH value or the level of free calcium ions (Ca^{2+}) also require ratio imaging to compensate for structural densities or section thickness [19].

Due to the anisotropic resolution of the data sets, various ways of improving axial resolution are available; *deconvolving methods* use the point spread function of the optics, which has to be measured first [108]. The algorithms can be differentiated further by their ability to incorporate noise. The classical filter is the Wiener filter; new developments include the iterative *maximum likelihood estimation* [109]. This method was extended with a blind deconvolution algorithm, using certain constraints to model the point spread function, which is a promising approach for biomedical users (see Fig. 21). However, calculation times are still in the range of 1 h for some hundred iterations. A different approach is the *nearest-neighbor deconvolution* developed for bright-field imaging [110], by taking into account the blur present in the planes above and below the focal plane. More recently, this method has been contrasted with a no-neighbor deconvolution method [111]. Besides directly improving data, isotropy can also be obtained by interpolating the lateral dimension [92]. Transformation of data from a cubic format into other lattices has also been proposed, based on mathematical morphology [112].

Sets in digital image processing to enhance, filter, segment, and identify structures are frequently applied to three-

dimensional microscopic data sets. This can be done either section by section or by using the corresponding three-dimensional extension of digital filters, such as the Gauss, Laplace, Sobel, and Median filter or noise removal algorithms [113-116]. Segmentation often requires interaction of the user, since automatic segmentation algorithms generally rely on the intensities of the voxels only. Once the binary images have been obtained, binary morphological operations using structuring elements for erosion and dilatation can be performed [117].

Digital measurements address the size and volume of structures, quantities, or forms and relation between volumetric subtleties. To measure volumes, all voxels that identify a certain structure are summed up. It is particularly difficult to measure the surface of structures, and most methods offer an estimation based only on stereological methods. Object counting in volumes usually requires the definition of guard boxes, which are moved throughout the volume. Objects falling into such boxes are evaluated by following certain stereological rules to avoid any bias. Stereological considerations are also used to estimate spatial statistics, such as numerical densities or nearest-neighbor distances; such methods have been used extensively in three-dimensional cytometry [132].

1.7.2. *3D Visualization*

Visualization of serial sections is the most frequently used computer technique in confocal microscopy, independent of specific applications [118-120]. Most commercial instruments have three-dimensional software implementations ready for the user. Three-dimensional objects are displayed on the computer screen by staking up the individual sections. Such techniques have been reviewed in several articles [121-124]. Besides surface rendering based on contours, volumetric representations that rely on the intensities of the voxels are the preferred techniques in confocal microscopy. A comparative assessment of both techniques is given in [125]. Reconstructions are presented three-dimensionally on a computer graphics screen by using either visual cues, animation, of stereoscopic displays.

One method used in *volume rendering* is to define imaginary rays through the volume (*ray-casting techniques*) [126, 127]. The way of casting is accomplished by the definition of certain projection geometry. Given a central projection, the angles of the rays are defined by the matrix of the screen and the center of projection. A common implementation traverses the data in a front-to-back order, which has the advantage that the algorithm can stop when a predefined property of the accumulation process has been reached. This class of methods is also referred to as *image order rendering*, since the matrix of the screen is used as the starting point for the accumulation process. Because of the projection geometry, such a ray-firing technique does not necessarily pierce the center of a voxel, and an interpolation has to be taken into account. To improve the output of ray- casting renderings, preprocessing of the voxel scenes may be performed as, for example, in the renditions of complex chromatin arrangements [116]. Modalities available in image order rendering include maximum projection (Fig. 22), integration, and surface mode (Fig. 18).

Figure 22. Volume rendering of a confocal sequence

The neural network of immunohistochemically stained cells, together with connecting fibers in the neural optical tract of hamsters is visualized by this projection

(Specimen courtesy of H. KORF, Zentrum für Morphologie, Frankfurt, Germany)

A much simpler geometry is realized in a parallel projection, such as in *object order rendering*. Here the volume is rotated according to the current viewing angle and then traversed in a back-to-front order [128]. During traversal, each voxel is projected to the appropriate screen pixel where the contributions are summed or blended, a situation that is referred to as compositing. During the accumulation process other properties of voxels besides the intensities may be considered, such as opacity, color, gradient values [129, 130], or the simulation of fluorescence processes (SFP) [131]. However, since volume rendering relies entirely on voxel attributes, it has some disadvantages if analytical representations are required. Therefore, elements of computer graphics are combined with volumetric renditions. Examples can be found in vector descriptions of volumetric data sets [132] or in geometric attributes expressing local properties and topologies that can be embedded in the three-dimensional reconstruction [122, 133].

1.8. High-Throughput Screening for Histopathology and Drug Development

The prevailing tissue diagnostic methods use histological staining protocols, which are the basis of most pathological assessments. Specimens prepared from tissue blocks or biopsies are embedded in paraffin, cut into 5–7 µm thick sections, placed on glass slides sized 20× 50 mm, and are stained with Hematoxilyn-Eosin (H&E). Complete imaging of such a glass slide at 20× microscopic magnification generates several hundred individual digital color images. Specialized robotic microscopes, some developed out of telepathology [134], allow scanning of a complete slide within minutes. These solutions have implemented a continuous stage movement. The information about focus levels to guide the auto-focusing mechanism is generated either prior to the scanning process by probing and interpolating randomly selected points on the slide, or by a parallel detection path that looks ahead and continuously determines focal-position information. These systems have been automated further by robotic slide–loading mechanisms that allow the scanning of hundreds of slides without any user interaction. The images are digitized, automatically assembled into montages, and saved to disk for automated analysis. These automated solutions can be used in conjunction with special preparation techniques such as tissue microarrays (TMA). The TMA is composed of hundreds of tissue cores on one slide. Such preparations can substantially increase the throughput of many investigations, specifically in those areas where tissues of many donors have to be compared, such as the testing of antibodies or identification of biomarkers [135, 136].

In drug discovery, advances in combinatorial chemistry and genomics have led to the development of high–throughput screening (HTS) for drug target development [137]. Conventional cell-based HTS assays rely on measuring single parameters from lysates of cell populations grown in multi-well high-density plates (whole-well average measurement), at

single time points (end-point format) with very limited temporal resolution and no spatial resolution. By using standard or more advanced plate readers it is possible to reach the speed requirement of HT primary campaigns for drug discovery. New screening approaches are referred to as “high–content screening (HCS)”. HCS relies on more sophisticated assays where the higher quality of the data being generated is believed both to increase the likelihood of discovery and to accelerate the profiling of successful drugs [138, 139]. A number of automated imaging platforms have been introduced to the market, and each instrument offers different solutions toward imaging and specimen handling, fluidics/kinetics capabilities, sample throughput, and data analysis to accomplish HCS. Some of these imaging workstations are confocal (based either on laser line or spinning disk) while some are not. Confocal imaging platforms support kinetics, such as calcium and sodium fluxes, mitochondria, and changes in plasma membrane potential. Also supported are end-point cell assays , e.g., cytotoxicity, apoptosis, cell cycle, translocations, using common commercially available fluorescent probes [140].

[Top of Page]

2. Electron Microscopy

Severin Amelinckx and Ludwig Reimer

2.1. Introductory Considerations [154]

There are two main classes of electron microscopy (EM) techniques. In the first class, the electron probe is a stationary beam incident along a fixed direction. This incident beam can be parallel [conventional transmission electron microscopy (CTEM), high-resolution transmission electron microscopy (HRTEM), high-voltage transmission electron microscopy (HVTEM), selected-area electron diffraction (SAED)] or convergent [convergent-beam electron diffraction (CBED), convergent-beam electron microscopy (CBEM)]. The resolution is determined by the quality of the imaging optics behind the specimen. Instruments implementing these techniques are conceptually related to classical light microscopes.

In the second class of methods, a fine electron probe is scanned across the specimen, and transmitted electron (TE) [scanning transmission electron microscopy (STEM)] or the desired excited signal such as secondary electrons (SE) or backscattered electrons (BSE) [scanning electron microscopy (SEM)], and/or AE [Auger Electron spectroscopy (AES)/scanning Auger microscopy (SAM)] is selected, detected, and the signal amplified and used to modulate the intensity of another electron beam which is scanned synchronously eith the first over the screen of a TV monitor. The stationary beam methods are based on image formation processes, whereas the scanning methods are essentially “mapping” techniques. Their resolution is mainly determined by the probe size, i.e., by its electron probe formation optics. The magnification is geometric; it is determined by the ratio of the areas scanned by the electron beam on the screen and synchronously by the electron probe on the specimen.

Analytical microscopes (AEM) have been developed which make it possible to implement a number of imaging modes, diffraction modes, and analytical modes in a single instrument and often also to apply them to a single specimen. The synergism of these tools has the potential to provide detailed structural and chemical information on the nanoscale. There is a trend of extending stationary beam probe analytical tools such as X-ray microanalysis, Auger electron spectroscopy (AES), and electron energy loss spectroscopy (EELS) into mapping methods which make it possible to image spatial distributions of chemical elements.

2.2. Conventional Transmission Electron Microscopy (CTEM)

2.2.1. *Introduction*

The images produced in transmission electron microscopy are essentially due to local diffraction phenomena; absorption contrast plays only a minor role. Not only is electron diffraction responsible for the image formation; it also allows establishment of the orientation relationship between direct space, as observed in the image, and reciprocal space as imaged in the diffraction pattern (see ⟶). Images and the corresponding diffraction patterns are equally important for a detailed interpretation; both should always be produced from the same selected area, with the specimen orientation unchanged. For this reason, most commercial microscopes have the ability to switch easily from the diffraction mode to the imaging mode and vice versa (see Section Operating Modes of the Electron Microscope).

2.2.2. *Scattering by Atoms: Atomic Scattering Factor*

Electrons are scattered by atoms as a result of Coulomb interaction with the nucleus and the electron cloud. The atomic scattering factor $f_e(\theta)$ thus contains two terms of opposite sign

$$f_e(\theta) = \frac{m e^2 \lambda}{2h^2}[z - f_x(\theta)] / \sin^2\theta \qquad (2.1)$$

where z is the atomic number; $f_x(\theta)$ the scattering factor for X-rays; m the electron mass; e the electron charge; λ the wavelength of the electrons; and h Planck's constant [155].

The first term clearly relates to the nucleus, whereas the second term is due to the electron cloud. The interaction with matter is stronger ($\times 10^4$) for electrons than for X-rays or neutrons, which interact only with the electron cloud or with the nucleus, respectively. As a result multiple scattering will not be negligible in electron diffraction experiments. Moreover, electron scattering is oriented mainly in the forward direction. Tables of $f_e(\theta)$ for different atoms are given in [156].

2.2.3. *Kinematic Diffraction by Crystals*

2.2.3.1. *Lattice, Reciprocal Lattice*

The amplitude diffracted by an assembly of atoms results from interference of the waves scattered by the atoms (i.e., the scattered amplitude in any given direction is obtained by summing the amplitudes scattered in that direction by the individual atoms and taking into account the phase differences due to path differences resulting from the geometry of the

assembly). For a physical and mathematical description of the important terms lattice and reciprocal lattice, see [157] and ⟶ .

2.2.3.2. *Geometry of Diffraction*

Bragg's Law [158]. Like other diffraction phenomena in periodic structures, electron diffraction can be described in either direct or reciprocal space. Bragg's diffraction condition describes diffraction in direct space. A diffracted beam will be formed whenever the incident beam encloses with the set of lattice planes an angle $\theta_{\mathbf{H}}$, such that the path difference 2 $d_{\mathbf{H}}$ sin $\theta_{\mathbf{H}}$ between waves diffracted by successive lattice planes is an integer *n* of wavelengths λ of the radiation used:

$$2d_{\mathbf{H}} \sin \theta_{\mathbf{H}} = n\lambda \tag{2.2}$$

where **H** denotes the Miller indices of the plane. In Figure 23 this path difference is indicated by a thicker line. For 100-kV electrons, λ = 4 pm, and as a result, the Bragg angles $\theta_{\mathbf{H}}$ are very small — a few degrees at most.

Figure 23. The derivation of Bragg's diffraction law in direct space

Ewald Construction [159]. Diffraction conditions can also be formulated in terms of reciprocal space as

$$\bar{\mathbf{k}} = \bar{\mathbf{k}}_0 + \bar{\mathbf{g}} \tag{2.3}$$

where $\bar{\mathbf{k}}_0$ is the wave vector of the incident electron beam and $\bar{\mathbf{k}}$ the wave vector of the diffracted beam, where $|\bar{\mathbf{k}}| = |\bar{\mathbf{k}}_0| = 1/\lambda$; $\bar{\mathbf{g}}$ is a reciprocal lattice vector. Equations (2.2) and (2.3) have the same physical content. They can be obtained by expressing the conservation of energy and of momentum of the incident electrons on scattering. More details on Ewald's construction are given in [160] and in ⟶ .

Diffraction by a Thin Foil. Since electrons are strongly “absorbed” in solids the specimen must be a thin foil (< 300 nm); otherwise no diffracted beams will be transmitted. The number of unit cells along the normal to the foil is thus finite, whereas along directions parallel to the foil plane, the number of unit cells can be considered infinite. In such specimens the diffraction conditions are relaxed, and diffraction also occurs for angles of incidence deviating somewhat from the Bragg angle. In reciprocal space this relaxation results in a transformation of the sharp reciprocal lattice nodes into thin rods (so-called relrods) perpendicular to the foil plane. The Ewald sphere intersects such a rod to produce a diffracted beam. The direction of this beam is obtained by joining the center of Ewald's sphere with this intersection point. The resulting diffraction pattern can to a good approximation be considered to be a planar section of the reciprocal lattice. Indexing of the diffraction spots is simple and unambiguous.

The distance $\bar{\mathbf{s}}_{\bar{\mathbf{g}}}$ by which the lattice node *G* is missed by Ewald's sphere is called the *excitation error.* It is a vector along the direction of the foil normal joining the reciprocal lattice node *G* to the intersection point with Ewald's sphere. It is positive when pointing in the sense of the incident beam and negative in the opposite case.

Column Approximation [161]. The small magnitude of the Bragg angles causes the electrons to propagate along narrow columns parallel to the beam direction. The intensity observed in a point at the exit face of the specimen is thus determined by the amplitude scattered by the material present in the column located at that point. In a perfect foil the intensity does not depend on the considered column, but when defects are present, it does.

Kinematic Rocking Curve. The amplitude of the beam scattered by a foil of thickness z_0 is obtained by summing the amplitudes scattered by the volume elements along a column perpendicular to the foil surface and taking into account the phase differences due to their depth position in the column. For a perfect foil the intensity of the scattered beam, I_s for reflection **H** is given by

$$I_s(s,\ z_0) = F_{\mathbf{H}}^2 \sin^2 \pi s z_0/(\pi s)^2 \tag{2.4}$$

where $F_{\mathbf{H}}$ is the structure factor [143] with indices **H**.

The dependence of I_s on *s* (i.e., on the direction of the incident beam and on the foil thickness z_0) is called the *rocking curve* (see Fig. 24). The separation of the zeros is $1/z_0$, and the full width of the central peak is $2/z_0$.

Figure 24. Plot of scattered intensity I_s versus excitation error, i.e., the “rocking curve” according to the kinematic approximation

Bent Contours [162]. For a curved foil, *s* varies along the specimen; the loci of constant *s*, imaged as bright and dark fringes, are called bent extinction contours. They form as shown schematically in Figure 25 for a cylindrically bent foil.

Figure 25. Formation of bent extinction contours by a cylindrically bent foil

Thickness Contours. The thickness dependence of I_s is periodic with period $1/s_{\bar{g}}$: the period thus diverges for $s_{\bar{g}} = 0$ (i.e., for the exact Bragg condition). The loci of equal thickness are also imaged as lines of equal intensity; they are called thickness extinction contours or wedge fringes.

Kikuchi Lines [163]. In rather thick specimens a second type of diffraction pattern becomes prominent, which consists mainly of lines rather than spots. These lines occur in parallel pairs; the line closest to the center of the diffraction pattern is darker, whereas the one further from the center is brighter than the background (Fig. 26). These lines are the intersections of Ewald's sphere with rather flat double cones having semiapex angles equal to 90° – θ_H, where θ_H is the Bragg angle associated with the pair of lines ($\theta_H \approx 1 – 2°$). The angular separation of the bright – dark line pair is 2 θ_H.

Figure 26. Kikuchi line pattern produced by a silicon foil

Note the parallel pairs of bright (excess) and dark (deficiency) lines. The deficiency lines are close to the center. The excess lines are separated in angle by 2 θ_H from the corresponding deficiency lines

If the Bragg condition for a set of lattice planes is satisfied exactly, the bright Kikuchi line associated with that set of planes will pass through the corresponding Bragg spot, whereas the dark one will pass through the origin. The separation of a Bragg spot from its corresponding Kikuchi line is a measure of the excitation error *s* of that reflection. As a result, the Kikuchi line pattern provides a means to measure *s* [164].

2.2.4. *Dynamic Diffraction by Crystals*

2.2.4.1. *General Considerations*

According to kinematic theory the intensity of diffraction spots is proportional to the square of the structure factor (Eq. 2.4). This simple proportionality is lost in reality because of multiple diffraction effects, which are taken into account adequately in dynamic theory [165].

Although kinematic theory does not predict the intensities of diffraction spots correctly, it is useful because the geometric features of diffraction are well described. For large *s* or very small foil thicknesses the relative spot intensities are qualitatively reproduced. For *s* = 0, kinematic theory breaks down since a diffracted beam with diffraction vector $\bar{g}_1$ may then acquire an amplitude comparable to that of the incident beam, and thus act as an incident beam and give rise to diffraction in the reverse sense (i.e., with diffraction vector $-\bar{g}_1$).

For most orientations of the incident beam, many diffracted beams are excited simultaneously and a section of reciprocal space is imaged. However by carefully orienting a sufficiently thick specimen the intensity of a single diffracted beam can be maximized: this is called a *two-beam case*. Such specimen orientations should be used, whenever possible, in the quantitative study of defects.

2.2.4.2. *Basic Equations*

The two-beam dynamic theory describes the interplay between transmitted and diffracted beams by means of a set of coupled differential equations of the form [144, 166].

$$\mathrm{d}T/\mathrm{d}z = (\pi i/t_{-g})S \exp 2\pi i s z \tag{2.5a}$$

$$\mathrm{d}S/\mathrm{d}z = (\pi i/t_g)T \exp -2\pi i s z \tag{2.5b}$$

where *T* and *S* are the complex amplitudes of the transmitted and scattered beams, respectively; *z* measures the depth in the foil. The exponential factors take into account the growing phase shift due to the excitation error, with increasing distance *z* behind the entrance face. The factor *i* takes into account the phase jump on scattering; t_g and t_{-g} are called the extinction distances. The extinction distance, which has the dimension of length, is a measure of the strength of the reflection $\bar{g}$. For low-order reflections of elemental metals it is of the order of a few tens of nanometers, but for weak superstructure reflections it may be several hundred nanometers. Whether a foil is “thick” or “thin” depends on the number of extinction distances in the foil thickness. Kinematic theory is valid only for foils with a thickness that is a fraction of an

extinction distance.

Absorption can phenomenologically be accounted for by assuming the extinction distances to be complex [167]. Formally $1/t_{\bar{g}}$ is replaced by $1/t_{\bar{g}} + i/\tau_g$, where τ_g is called the absorption length. Empirically, it is found that τ_g ranges from $5\,t_g$ to $15\,t_g$. The substitution can be made, either in the Equation set (2.5) or directly in the solution of this set.

2.2.4.3. *Dynamic Rocking Curve*

By ignoring absorption and taking into account the fact that $T = 1$ and $S = 0$ at $z = 0$ (entrance face), integration of Equation set (2.5) gives

$$T(s,z) = [\cos \pi\sigma z - i(s/\sigma)\sin \pi\sigma z] \exp \pi i s z \tag{2.6a}$$

$$S(s,z) = (i/\sigma t_g) \sin \pi\sigma z \exp \pi i s z \tag{2.6b}$$

and thus

$$I_s = SS^* = (1/\sigma t_g)^2 \sin^2 \pi\sigma z \tag{2.7}$$

$$I_T = 1 - I_s \tag{2.8}$$

where

$$1/\sigma = t_g/(1 + s^2 t_g^2)^{1/2} \tag{2.9}$$

For $s = 0$ this reduces to $\sigma = 1/t_g$ (i.e., the depth period is now $t_{\bar{g}}$ and for large s: $\sigma = s$). The divergence of kinematic theory for $s = 0$ is now removed. The depth variation of the transmitted and scattered beams, leading to thickness extinction contours, is represented schematically in Figure 27 for $s = 0$ as well as for $s \neq 0$.

Figure 27. Interplay between incident and diffracted beam according to the dynamic theory

A) Bragg's condition is satisfied exactly, the depth period is t_g; I_S and I_T pass periodically through zero; B) $s \neq 0$ the depth period is now $1/\sigma_g$; I_T varies periodically but does not pass through zero; I_S and I_T are complementary since absorption was neglected

2.2.4.4. *Anomalous Absorption, Bormann Effect [167, 168]*

Taking absorption into account gives more complex rocking curves of the type shown in Figure 28 for a foil of thickness $t = 3\,t_g$ and $\tau_g = 10\,t_g$. The curve for the diffracted beam (b) is symmetric, whereas the curve representing the transmitted beam (a) is asymmetric in s. For the same absolute value of s, the transmitted intensity is larger for $s > 0$ than for $s < 0$. This asymmetry is known as the Bormann effect; it was demonstrated initially for X-ray diffraction under dynamic conditions [168]. The steep change of I_T with s in the vicinity of $s = 0$ causes a large sensitivity of I_T to small changes in orientation.

Figure 28. Rocking curves for transmitted (a) and scattered (b) beams according to the two-beam dynamic theory, with anomalous absorption taken into account

2.2.4.5. *Lattice Fringes [169]*

The Electron Wave Function at the Exit Face. The amplitude of the transmitted wave for a unit incident wave can be represented by $T \exp 2\pi i \bar{K} \cdot \bar{r}$, where $\bar{K}$ is the wave vector of the incident wave inside the crystal (i.e., corrected for refraction at the vacuum – crystal interface). Similarly the diffracted wave can be represented by $S \exp 2\pi i(\bar{K} + \bar{g}) \cdot \bar{r}$, where $\bar{g}$ is the diffraction vector (i.e., the reciprocal lattice vector corresponding to the excited reflection). The wave function of the electrons emerging at the exit face of the foil is then

$$\psi = (T + S \exp 2\pi i \bar{g} \cdot \bar{r}) \exp 2\pi i \bar{K} \cdot \bar{r} \tag{2.10}$$

The observed intensity

$$I_\psi \equiv \psi\psi^* = I_T + I_S + 2\sqrt{I_T I_S} \sin (2\pi g x + \varphi) \tag{2.11}$$

with

$$\tan \varphi = (s/\sigma) \tan \pi\sigma t; \tag{2.12}$$

x is measured along the exit surface in the direction of $\bar{g}$: further, the following abbreviations are used: $I_T \equiv T\,T^*$; $I_S \equiv S\,S^*$. This expression represents sinusoidal fringes with a period $1/|\bar{g}|$; they can be considered as forming an image of the lattice planes $\bar{g}$.

2.2.4.6. *Faulted Crystals*

Planar Interfaces. Planar interfaces are imaged as fringes parallel to the foil surface; their characteristics depend on their geometric features. *Translation interfaces* (stacking faults, out-of-phase boundaries, etc.) separate two crystal parts related by a parallel translation $\bar{R}$ (Fig. 29 A), and *domain boundaries* separate domains that differ slightly in orientation (i.e., for which the excitation errors are different $\Delta s = s_1 - s_2$; (Fig. 29 B) [170].

Figure 29. Schematic of two different types of interfaces

A) Translation interfaces with constant displacement vector $\bar{R}$; B) Domain boundary between two regions for which the excitation error is slightly different; the displacement R increases with increasing distance from the interface (the homologous diffraction vectors $\bar{g}_1$ and $\bar{g}_2$ are slightly different: $\Delta\bar{g} = \bar{g}_2 - \bar{g}_1$)

Diffraction Equations for Faulted Crystals. The displacement over R_0 (R_0 = constant) of the exit part of a column with respect to the entrance part (Fig. 29 A), the two parts being separated by a fault plane, can be accounted for by noting that a supplementary phase change $\alpha = 2\pi\bar{g}\cdot\bar{R}$ occurs on diffraction but not on transmission (see Fig. 30). The path difference Δ between diffracted waves 1 and 2 is $\Delta = 2\,R_0 \sin\theta_H$, where θ_H is the Bragg angle and hence $2\,d_H \sin\theta_H = \lambda$ with $d_H = 1/|\bar{g}|$. This gives for the phase change $\alpha = (2\pi/\lambda)\,\Delta = 2\pi\,\boldsymbol{g}\,R_0$, where R_0 is in general the component of $\bar{R}$ along $\bar{g}$ (i.e., $gR_0 = \bar{g}\cdot\bar{R}$).

Figure 30. Diffraction by a faulted crystal

A) Effect of a translation interface with vector $\bar{R}_0$; B) Effect of a displacement field $\bar{R}(\bar{r})$; C) Schematic of the expressions for transmitted and scattered beam amplitude for a foil containing a general interface parallel to the foil surfaces

The equations describing diffraction by the displaced exit part are obtained by the substitution $S \longrightarrow S \exp -i\alpha$ in Equations (2.5). The amplitudes T and S emerging from a column intersecting such an interface are then obtained by integrating the Equation (2.5) set along a column down to the level of the interface and subsequently further down to the exit face, using the adapted form of Equation (2.5)(Fig. 30).

The effect on T and S of the presence of a defect described by a displacement field $\bar{R}(\bar{r})$ (for instance due to a dislocation) (Fig. 30) can be taken into account in Equations (2.5) by replacing the constant s by an effective local value s_{eff} which now depends on z, i.e., on the depth along the columns, and which is given by $s_{eff} = s + \bar{g}(d\bar{R}/dz)$. This can be shown rigorously but it can also be understood intuitively by the following geometrical considerations (Fig. 30 B).

Let the diffraction vector of the considered set of lattice planes be $\bar{g}$ at the level z below the entrance face. At level $z + dz$ the displacement $\bar{R}$ has increased by $d\bar{R}$ and as a result the local vector $\bar{g}$ is rotated over a small angle $\delta\theta \simeq \tan\theta = dR/dz$. The change in s corresponding to this rotation of $\bar{g}$ over $\delta\theta$ is given by $\delta s = g\,\delta\theta$, i.e., by $\boldsymbol{g}\,(dR/dz)$ or somewhat more general by $d(\bar{g}\cdot\bar{R})/dz$, expressing that only displacements which change the orientation of the vector $\bar{g}$ are operative.

In the particularly simple case of a domain boundary as modeled in Figure 29 B, $R = kz$ (k = constant) in the exit part. Hence, at the level of the domain boundary, s changes abruptly into $s + k$ along the integration column.

Diffraction by a Crystal Containing a Planar Interface [171]. The amplitudes of the transmitted and scattered beams for a foil containing a planar interface, with displacement vector $\bar{R}$ (Fig. 30 B), can be formulated as

$$T(s_1, s_2, z_1, z_2, \alpha) = T_1(s_1, z_1)\,T_2(s_2, z_2) + S_1(s_1, z_1)\,S_2(-s_2, z_2)\,\exp\,i\alpha \tag{2.13}$$

$$S(s_1, s_2, z_1, z_2, \alpha) = T_1(s_1, z_1)\,S_2(s_2, z_2)\cdot\exp\,(-i\alpha) + S_1(s_1, z_1)\,T_2(-s_2, z_2) \tag{2.14}$$

with $\alpha = 2\pi\bar{g}\cdot\bar{R}$. These relations can also be derived from the adapted set of Equation (2.5).

The first equation states that the amplitude of the transmitted beam T results from the interference between the doubly transmitted beam (i.e., the beam transmitted by the first part T_1 and subsequently transmitted by the second part: $T_1 \times T_2$)

and the doubly scattered beam $S_1 \times S_2^{(-)} \exp i\ \alpha$. The factor $\exp i\ \alpha$ takes into account the phase shift on the amplitude S_2 scattered by the second part, resulting from the translation of the second part of the foil.

A similar interpretation can be given to the second expression. The amplitudes $T_1(s_1, z_1)$, $T_2^{(-)}$, $S_1^{(-)}$, $S_2^{(-)}$ are given by Equations (2.6 a) and (2.6 b). The indices 1 and 2 refer to the entrance and exit parts, respectively: the minus superscript means that in the corresponding Equations (2.6 a) and (2.6 b), s must be replaced by $-s$, because diffraction occurs from the negative side of the set of lattice planes (i.e., the diffraction vector is $-\bar{g}$).

If $s_1 = s_2$ but $\alpha \neq 0$, Equations (2.13) and (2.14) refer to a pure translation interface. If $s_1 \neq s_2$ and $\alpha = 0$, the expressions are applicable to a domain boundary. For mixed interfaces, $s_1 \neq s_2$ as well as $\alpha \neq 0$. If the interfaces are parallel to the foil surfaces, transmitted and scattered intensities are constant over the specimen area, but they vary in a pseudoperiodic fashion with the thicknesses z_1 and z_2 of entrance and exit parts, with $z_1 + z_2 = z_0$ (total thickness). The expressions describing this variation explicitly are obtained by substituting Equations (2.6 a) and (2.6 b) into (2.13) and (2.14).

If the interfaces are inclined with respect to the foil surfaces this depth variation is displayed as a pattern of fringes parallel to the foil surfaces in the area where the two wedge-shaped crystal parts overlap.

The fringe profiles of α-fringes ($s_1 = s_2$; $\alpha \neq 0$) and δ-fringes ($\Delta s = s_1 - s_2 \neq 0$; $\alpha = 0$) in bright field (BF) and dark field (DF), exhibit different properties. The symmetry properties allow the fringe patterns due to the two kinds of interfaces to be distinguished. The properties of α-fringes with $\alpha = \pi$ are singular [172].

2.2.4.7. *Moiré Patterns [173-175].*

The superposition of two identical crystal foils having a small orientation difference θ (rotation moiré) or of two parallel crystal foils with a small difference in lattice parameters (parallel moiré) gives rise to a fringe pattern, which can to a good approximation be considered as the coincidence pattern of the lattice fringes corresponding to the diffraction vectors $\bar{g}_1$ and $\bar{g}_2$ active in the two crystal foils.

The fringes are parallel to the average direction $\bar{g}$ of the two diffraction vectors $\bar{g}_1$ and $\bar{g}_2$ in the case of rotation moiré patterns and perpendicular to the common direction of the two diffraction vectors in the case of a parallel moiré. From the moiré spacing Δ, small differences can be deduced in the lattice parameters d_1 and d_2 of the two components of the sandwich since $\Delta = d_1 d_2/(d_1 - d_2)$, or the small orientation difference $\theta = |\Delta\bar{g}|/|\bar{g}|$ in the case of a rotation moiré. Figure 31 shows an optical analogue for the two types of moiré fringes produced by the superposition of two line patterns.

Figure 31. Optical analogue for the formation of moiré fringes in a sandwich crystal

(Upper) The two crystals are parallel, but the lattice parameters are slightly different; (Lower) The two crystal parts exhibit a slight orientation difference

2.2.5. ***Operating Modes of the Electron Microscope [144, 146, 147]***

2.2.5.1. *Microscope Optics*

The ray paths in an electron microscope are shown in Figure 32, according to the geometrical optics approximation, for the two main operating modes: high-magnification, high-resolution imaging, and selected area diffraction.

Figure 32. Schematic of the beam path in an electron microscope according to the geometrical optics approximation

A) High-magnification, high-resolution mode; B) Selected area diffraction mode

a) Specimen; b) Objective aperture; c) Objective lens; d) Field-limiting aperture; e) Gaussian image plane; f) Intermediate lens; g) Projector lens

The microscope is essentially a three-lens system: an objective lens (c), an intermediate lens (f), and a projector lens (g). Each lens may be a composite lens. A movable selector aperture (b) is present in the image plane of the objective lens; a second aperture (d) is placed at the objective lens, close to the back focal plane. With the first aperture a small area (≤1 µm) of the image (i.e., of the specimen) is selected, with the second aperture a single beam is selected or a number of the image-forming diffracted beams.

The characteristics of the objective lens are crucial because they determine to a large extent the image resolution and the contrast. The other two lenses mainly provide the desired magnification.

Although magnetic lenses normally rotate the image about the optical axis, in microscopes designed at the end of the 1980s, these rotations are compensated by a suitable device, and the image and the diffraction pattern have the same orientation.

2.2.5.2. *High-Resolution, High-Magnification Mode*

In the first (Fig. 32) imaging ray path the beam produced by a source (tungsten filament, LaB_6, field emission gun; see also Section Electron Guns) and collimated by a condenser lens system, is scattered by the object, and an image is formed in the image plane of the objective lens. By means of the selector aperture, an area of the specimen is selected and magnified by the intermediate lens, which is focused on the image plane of the objective lens and provides a magnified image in the image plane of the intermediate lens. This image serves as the object for the projector lens, which forms the final image either on a fluorescent screen, on a photographic plate, or on an image intensifier followed by a TV camera. In the latter case — which is virtually a requirement for successful high-resolution work — the image can be viewed on a TV monitor and the final adjustments performed before the image is recorded photographically. Electronic recording on tape is of course possible directly via the TV signal; this mode is used mainly for so-called in situ dynamic studies.

2.2.5.3. *Diffraction Mode (Figure 32 B)*

When operating in the diffraction mode the intermediate lens (f) is weakened (i.e., its focal length is enlarged) so as to cause the back focal plane of the objective lens (c) to coincide with the object plane of the projector lens (g). This produces a magnified image of the diffraction pattern. In doing so, the selected area is not changed since only the intermediate lens current is changed; the diffraction pattern is thus representative of the selected area. The area selected in the diffraction mode is much larger than the field of view under high-resolution conditions.

As the electron beam passes through the specimen, various interactions occur next to diffraction: characteristic X-rays are produced, the electrons suffer energy losses, etc. These effects can be used for analytical applications (see Section Analytical Methods).

2.2.6. ***Selected-Area Electron Diffraction (SAED)***

ED methods (SAED, CBED) are a useful complement to X-ray diffraction, especially when the material is available only as small microcrystals. Then only powder diffractometry can be applied when using X-rays. However, even fine powders usually contain single crystals of a sufficient size to produce a single-crystal ED pattern that allows the approximate (but unambiguous) determination of the lattice parameters. These approximate lattice parameters in turn allow unambiguous indexing of the powder diffraction pattern and subsequently make possible a precise lattice parameter measurement. In addition, ED patterns often exhibit weak reflections due to superstructures, which are not visible in X-ray powder diffraction.

The spatial geometry of diffuse scattering can be reconstructed more easily from ED patterns than from X-ray diffraction patterns, since ED patterns are planar sections of reciprocal space, which is not the case for X-rays.

2.2.7. ***Diffraction Contrast Images [144, 164]***

2.2.7.1. *Imaging Modes*

Diffraction contrast images are usually obtained under two-beam conditions. By means of the aperture placed close to the back focal plane of the objective lens, either the transmitted or the diffracted beam is selected and the corresponding diffraction spot is highly magnified (Fig. 33). The image obtained in this way is a map of the intensity distribution in the selected diffraction spot. The image made in the transmitted beam is a *bright-field image*, whereas the image made in the diffracted beam is a *dark-field image*. Since the electrons are confined to narrow columns, the latter can be considered the picture elements of this image. The amplitude of the transmitted (or scattered beam) associated with a point at the back surface of the specimen is obtained by summing the contributions of the volume elements along a column parallel to the incident beam centered on that point. The amplitude depends on how the excitation error *s* changes along the column, which in turn varies with changes in the orientation of the diffracting planes along the column. Strain fields cause such orientation changes and can thus be imaged in diffraction contrast. Diffraction contrast images do not reveal the crystal structure but are very sensitive to the presence of strain fields caused by defects such as dislocations.

Figure 33. Schematic representation of different imaging modes

A) Bright-field diffraction contrast mode; B) Dark-field diffraction contrast mode; C) High-resolution imaging mode

a) Specimen; b) Lens; c) Aperture; d) Screen

2.2.7.2. *Dislocation Contrast [141, 144]*

Consider a foil (Fig. 34) containing an edge dislocation in E, with an orientation such that in the perfect parts of the foil the amplitude of the incident beam is approximately equally divided between the transmitted and the diffracted beams. To the left of the dislocation the considered lattice planes are locally inclined in such a way as to better satisfy Bragg's condition (i.e., *s* is smaller) than in the perfect parts; more electrons are diffracted than in the perfect part. A lack of intensity will then be noted left of the dislocation in the transmitted beam, leading to a dark line in the bright-field image. At the right of the dislocation, Bragg's law is less well satisfied than in the perfect part. This leads to a lack of intensity in the scattered beam and thus to a dark line in the dark-field image. The image is on one side of the dislocation: the side on which the dark line occurs in the bright-field image is called the *image side*. According to this model the image side is where the lattice planes are tilted into the Bragg orientation.

Figure 34. Schematic representation of the image formation at an edge dislocation in a thin foil

The line thickness is a measure of the beam intensity. The image profiles for bright-field (BF) and dark-field (DF) images are represented schematically along with diffraction conditions in the perfect part of the foil

The conditions for kinematic diffraction [176] are best approximated in the *weak-beam* method, which consists of making a dark-field image in a weakly excited diffraction spot. The dislocation image then consists of a narrow bright line on a darker background.

2.2.7.3. *Extinction Conditions for Defects*

Diffraction by a family of lattice planes that remain undeformed by the presence of the dislocation will not produce an image of the dislocation [144, 177].

Quantitative images based on dynamic theory can be computer simulated by using the methods developed in [178]. A comparison of simulated and observed images allows determination of all the relevant parameters of various dislocation types (Fig. 35). More details are given in [179].

Figure 35. Examples of computed images (right) and the corresponding observed images (left) of the same dislocation by using different diffraction vectors [178]

2.2.7.4. *Domain Textures*

Phase transitions in crystals are usually accompanied by changes in symmetry, the space group of the low-temperature phase being a subgroup of the space group of the high-temperature phase. On cooling, the crystal breaks up into *orientation variants* (or twins) related by the lost symmetry elements of the high-temperature phase and *translation variants* (out-of-phase boundaries) related by the lattice translations lost on forming the superlattice [180]. The composite diffraction pattern of a domain texture is the superposition of the diffraction patterns due to individual domains. The diffraction pattern taken across a *reflection twin interface* contains one row of unsplit spots, which is perpendicular to the mirror plane. All other diffraction spots are split along a direction parallel to the unsplit row of spots [143].

In diffraction contrast images made in a cluster of *split diffraction spots*, orientation domains exhibit differences in brightness (i.e., domain contrast), especially for conditions close to $s = 0$ where the intensity variation with s is steep (Fig. 36). The presence of translation variants is not reflected in the diffraction pattern, except by some diffuse scattering.

Figure 36. Domain texture in β-lead orthovanadate resulting from the $\gamma \longrightarrow \beta$ transformation

A) The central triangular area still consists of the high-temperature γ-phase, whereas the other domains are in the low temperature β-phase; B) The same area as A) after additional cooling. The unstable triangular γ-area has been reduced further (Courtesy of C. Manolikas)

Images made in *unsplit reflections* do not reveal brightness differences due to orientation differences of the lattice, but they may exhibit domain contrast due to differences in the structure factor. This is the case for Dauphiné twins in quartz, which are related by a 180° rotation about the threefold axis (Fig. 37). The two domains produce the same diffraction pattern since their lattices are common, but certain reflections have structure factors that differ in magnitude [181]. A dark-field image made in such a reflection will exhibit a different brightness in the two domains, which is called the structure factor contrast [144].

Figure 37. Dauphiné twin lattice in α-quartz close to the phase transition into the high-temperature β-phase viewed along the threefold axis

A temperature gradient is established across the specimen area. The α-phase is broken up in regular arrays of columnar domains whose size decreases with increasing temperature [181]

2.2.7.5. *Interface Contrast and Domain Contrast*

Interface contrast (i.e., an α-fringe pattern) is produced in the projected area of the interface even if the structure factors in the two domains have the same magnitude, but differ in phase by α; no domain contrast is produced under these conditions. Interface contrast is also produced at *orientation domain boundaries*; δ-fringes are produced in the projected area, since the *s*-values on both sides of the boundary are different in general [182]. Extinction of the δ-fringe pattern occurs if the *s*-values are the same for the two domains.

The presence or absence of domain contrast across a fringe pattern helps to distinguish the two types of interface. If the two domains on either side of the interface exhibit the same brightness for all reflections, the fringes must be due to a translation interface; they must exhibit α-character. Domains exhibiting a difference in brightness are separated by a domain boundary and the fringes are of the δ-type.

2.2.7.6. *Strain Field Contrast*

The strain field associated with precipitate particles in a matrix whose lattice parameters differ slightly from those of the precipitate can also be revealed as regions of different brightness [183]. For example, a spherical particle in an elastically isotropic matrix produces a spherically symmetric strain field. In certain parts of this strain field the vector $\bar{R}$ is locally perpendicular to $\bar{g}$; such areas will show up with the background brightness. In other areas, $\bar{g}$ is parallel to $\bar{R}$; such areas will show up with a brightness that is different from the background, either lighter or darker.

2.2.8. *Convergent Beam Diffraction [148, 184]*

2.2.8.1. *Geometry of Convergent Beam Patterns*

In the early 1980s, a class of applications based on the use of a convergent beam of electrons (convergent beam diffraction, CBD) was developed. Whereas parallel beams allow high spatial resolution, *high angular resolution* is more easily achievable with convergent beams. For these applications the electrons are incident along directions within a cone of revolution or along the surface of a cone (hollow cone method) having its apex in (or close to) the sample plane. Under these conditions, electrons are incident on the specimen under all possible directions within a certain angular range, which should be of the order of the Bragg angles of the lowest-order reflections of the material under study. In practice, the semiapex angle α varies from 2 to 10 mrad. Also, the corresponding diffracted beams for each reciprocal lattice node form cones. The intersections of these cones with the photographic plate are circular disks whose radii are proportional to the semiapex angle of the cone of incident directions (Fig. 38). If the specimen is perfectly flat and defect free, these disks are images of the angular intensity distribution in each particular reflection.

Figure 38. Production of a convergent beam electron diffraction pattern

a) Probe forming optics; b) Specimen; c) Film

The incident beam is convergent. Diffraction disks are centered on each diffraction spot.

2.2.8.2. *Point Group Determination [185, 186]*

When the incident beam is parallel to a zone axis, the symmetry of the intensity distribution in the complete disk pattern, including the fine lines in the 000 disk, reflects the point symmetry of the crystal along this zone axis (Fig. 39).

Figure 39. Zone axis convergent beam electron diffraction pattern revealing the presence of a sixfold rotation axis [184]

Several techniques can be used to determine the point group [185]. The method developed by BUXTON et al. [186] is based on the use of zone axis patterns and of dark-field diffraction patterns obtained under exact two-beam conditions. By choosing the appropriate optical conditions, these disks do not overlap and the exact Bragg spots remain in the centers of the corresponding disks. The optics required for the application of these methods are described in [187]. With increasing cone angle the disks start to overlap and the nature of the pattern changes, but the symmetry elements are conserved.

A disk in the CBED pattern usually consists of broad fringes due to the dynamic interaction between beams belonging to the zero-order Laue zone (ZOLZ). Finer lines are formed by the interaction of high-order Laue zone reflections (HOLZ) with the zero-order beams (Fig. 40). The geometry of the HOLZ lines is determined by the accelerating potential and the lattice parameters; comparison of computer-simulated and observed patterns allows determination of one parameter if the other is known [187, 188].

Figure 40. Deficiency HOLZ (high-order Laue zone) lines in the central disk of a convergent beam diffraction pattern of

silicon [184]

2.2.8.3. *Space Group Determination*

Space group determination is based on the observation of the Gjønnes – Moodie lines [189] in certain “forbidden” diffraction disks. Reflections that are kinematically forbidden may appear as a result of double diffraction under multibeam dynamic diffraction conditions. If such forbidden spots are produced along pairs of different symmetry-related diffraction paths that are equally excited, the interfering beams may be exactly in antiphase for certain angles of incidence if the structure factors have opposite signs. Since the convergent beam disks are formed by beams with continuously varying directions of incidence, this condition will always be satisfied somewhere in the disk. The locus of points for which the phase difference is exactly π is a dark fringe along a diameter of the disk for which the Bragg condition is satisfied exactly (Gjønnes – Moodie lines, Fig. 41).

Figure 41. Convergent beam electron diffraction pattern exhibiting Gjønnes – Moodie lines due to the presence of glide mirror planes and twofold screw axis [184]

2.2.8.4. *Foil Thickness Determination*

From the dark-field two-beam rocking curve (Section Geometry of Convergent Beam Patterns) observed in the disk corresponding to the diffracted beam, the specimen thickness can be deduced with high accuracy provided the accelerating voltage and the interplanar spacing of the excited reflection are known [190].

2.2.9. ***High-Resolution Electron Microscopy***

In recent years, high-resolution electron microscopy has become an important tool in the study of complicated crystal structures and their defects. Whereas detailed considerations of electron optics are of only marginal importance in the case of diffraction contrast images, they become essential for a discussion of the atomic resolution structure images produced by crystals.

2.2.9.1. *Image Formation in an Ideal Microscope (Fig. 42)*

Figure 42. Image formation in an ideal microscope

a) Specimen; b) Objective lens; c) Back-focal plane, objective aperture; d) Image plane

The diffraction pattern Q (u, v) is the Fourier transform of the object q (x, y); the image is the inverse Fourier transform Ψ (x, y) of the diffraction pattern

Let the crystalline object be a thin foil characterized by a two-dimensional transmission function q (x, y) that describes at each point of the exit surface of the specimen the amplitude and phase of the electron beams emerging from the column situated at (x, y) after dynamic diffraction in the foil. The diffraction pattern can be described to a good approximation as the Fourier transform Q (u, v) of the object function q (x, y). This diffraction pattern acts in turn as a source of Huyghens wavelets, which interfere to form the image, after linear magnification by the optical lens systems; the image is, in turn, the Fourier transform Ψ (x, y) of the diffraction pattern.

2.2.9.2. *Image Formation in a Real Microscope*

In real microscopes the situation is complicated by the presence of finite apertures and lens aberrations. The apertures truncate the Fourier transform by admitting only a finite number of beams to the image formation process. Lens aberrations depend on the angle β that a diffracted beam encloses with the optical axis of the microscope, hence they introduce angle-dependent phase shifts between diffracted beams. Moreover, they cause “blurring” of the image, a point of the object plane being represented as a disk in the image plane and vice versa.

Spherical Aberration. Spherical aberration causes electron beams enclosing an angle β with the optical axis to suffer a phase shift χ_S with respect to the central beam:

$$\chi_S = \frac{1}{2}\pi\, C_S \beta^4/\lambda \tag{2.15}$$

where C_S is the spherical aberration constant.

Defocus. Under exact Gaussian focusing conditions the contrast produced by an object that changes only the phase of the incident electron wave (i.e., a so-called phase grating) is minimal. This is the case for thin crystalline foils. Visual contrast improves when working in underfocused conditions. The phenomenon is in a sense similar to phase contrast in optical microscopy of phase objects. Defocusing causes a relative phase shift of the diffracted beams enclosing different angles with the central beam. The phase shift caused by a defocus distance ε with respect to the Gaussian focus is given by

$$\chi_D = \pi\, e\, \beta^2/\lambda \tag{2.16}$$

The total phase shift caused by spherical aberration and defocusing is thus:

$$\chi(\beta) = \left(\frac{1}{2}\pi\, C_S \beta^4 + \pi\, e\, \beta^2\right)/\lambda \tag{2.17}$$

$\chi(\beta)$ depends on β in the way shown in Figure 43, i.e., there is a flat minimum at $\beta_{min} = (-\varepsilon/C_S)^{1/2}$ and a zero at $\beta = (-2\ \varepsilon/C_S)^{1/2}$.

Figure 43. Dependence on β of the phase shift $\chi(\beta)$ of a beam enclosing an angle β with the optical axis of the microscope

Phase Grating Approximation [191]. The effect of this phase shift on the image parameter can be understood most easily by discussing the case of a pure phase grating, which is a reasonable model for a very thin crystalline foil. Such a specimen causes a phase shift χ of the electron wave on passing through the foil because the wavelength of the electron is different in vacuum and in the crystal. This phase shift in the point (x, y) can be written as $\sigma\, \Phi(x, y)$ where Φ is the projected potential integrated over the sample thickness along the propagation direction of the electrons, and $\sigma = \pi/\lambda E$ (λ = wavelength of electron in vacuum; E = accelerating voltage). Ignoring absorption, the object function for a thin foil can be written as

$$q(x, y) = \exp\, i\sigma\varphi(x, y) \simeq 1 + i\sigma\varphi(x, y) \tag{2.18}$$

Taking also into account the phase shift (Eq. 2.17) caused by the lens system on the diffracted beams, and neglecting absorption it can be shown by Fourier transformation [192] that the image intensity is finally given by

$$I(x, y) \simeq 1 - 2\sigma\varphi(x, y) \tag{2.19}$$

whereby it was assumed that $\sin\chi = -1$ ($\cos\chi = 0$). The image contrast, defined as $(I - I_0)/I_0 = -2\ \sigma\ \Phi(x, y)$, where I_0 is the incident intensity, is thus directly proportional to the projected potential $\Phi(x, y)$ provided $\sin\chi = -1$.

Provided $\sin\chi = -1$, columns of large projected potential are imaged as dark dots. If $\sin\chi = +1$, the same columns would be imaged as bright dots.

Optimum Imaging Conditions. The most stringent requirement is $\sin\chi = -1$; this condition can only be met approximately and only in a limited β interval. The condition $\sin\chi = +1$ can be satisfied only for a limited number of discrete β-values.

The situation is somewhat comparable to positive and negative phase contrast in optical microscopy. The lens imperfections have been used to introduce a phase shift of $\pi/2$ in the same way as the quarter wavelength ring in the optical microscope. Only beams passing through the "window" in which the condition $\sin\chi = -1$ is met, interfere with the required phase relationship that causes the image to represent maxima in projected potential as dark areas.

From Equation (2.17) it is clear that $\chi(\beta)$ depends on the parameters C_S, ε, and λ. The condition $\sin\chi = -1$ can thus be met by adjusting one or several of these parameters. For a given instrument C_S and λ are fixed and the observer can meet this condition by optimizing the defocus ϵ. From Equation (2.17) it follows that χ adopts the essentially negative value $\chi = -\pi\ \epsilon^2/(2\ \lambda\ C_S)$ for $\beta = (-2\ \epsilon/C_S)^{1/2}$. $\sin\chi$ will be -1 if $\pi\ \epsilon^2/(2\ \lambda C_S) = \pi/2$, i.e., for

$$e_S = -(\lambda\, C_S)^{1/2} \tag{2.20}$$

For the defocus $\epsilon = \epsilon_S$ the curve $\sin\chi$ versus β will exhibit a rather flat part in the region around

$$\beta = (-e/C_S)^{1/2} \tag{2.21}$$

where $\sin\chi = -1$. The underfocus value ϵ_S corresponding to this optimum is called Scherzer defocus [193]. Most high

resolution images are made under this defocus condition and in the thinnest part of the sample.

2.2.9.3. *Resolution Limiting Factors*

Aperture. The presence of an aperture admitting only beams that enclose an angle with the optical axis not exceeding β_A imposes a resolution limit, called the Abbe limit [194]. A point in object space is imaged as a circle with a radius

$$\varrho_A = 0.61\lambda/\beta_A$$

Chromatic Aberration. Instabilities ΔE in the high voltage E of the microscope cause a spread in the wavelength of the incident electron, which blurs the image. Variation ΔI in the lens current I similarly causes a spread in the focal length of the lenses, which also contributes to such blurring. Furthermore, the inelastic scattering of electrons in the specimen causes slight changes in the wavelength of electrons emerging from the specimen. The net result of these different phenomena can be described as an effective spread in the focal length of the objective lens:

$$\Delta f = C_C\left[(\Delta E/E)^2 + 4(\Delta I/I)^2\right]^{1/2} \tag{2.22}$$

where C_C is the chromatic aberration constant; the corresponding disk of least confusion in object space is $\varrho_C = \beta\ \Delta f$. In concrete cases, $\Delta E/E \leq 10^{-6}$; $\Delta F \approx 10$ mm, $C_C \approx 10$ mm.

Astigmatism. Ideal lenses should have cylindrical symmetry. However, in reality, slight deviations may occur, leading to a dependence of the focal length on the azimuth of the ray path considered. Astigmatism can occur for various reasons, including inhomogeneities in the polepiece material, asymmetry in the windings, or a dirty aperture. As a result of astigmatism a point source is imaged as two different line foci at right angles to each other. At exact focus the image deformation disappears but the image is still blurred. Astigmatism can be corrected by a stigmator — a device (usually an octopole) that makes the lens appear perfectly cylindrical — by applying weak additional magnetic fields. Careful correction of astigmatism is essential for the production of high-quality, high-resolution images.

Beam Divergence. The intense illumination required for high-resolution imaging is obtained by a condenser lens system that produces a slightly conical beam with a typical apex angle of the order of 10^{-3} rad. This also leads to some image blurring since the final image is the superposition of images corresponding to the different directions of incidence.

Mechanical Instability. The obtainable resolution depends not only on the lens characteristics but also to a large extent on the mechanical stability of the microscope, which should be installed on a vibration-free heavy concrete block. In many cases the mechanical stability is actually the resolution-determining factor. The specimen holder should moreover be creep free, which is a problem for hot and cold stages. High-resolution work is therefore performed almost exclusively at room temperature.

Ultimate Resolution. The final disk of confusion due to the different nonmechanical blurring effects is given approximately by

$$\varrho = (\varrho_A^2 + \varrho_S^2 + \varrho_C^2)^{1/2} \tag{2.23}$$

which depends on β. At low angles the aperture effect is usually dominant, whereas at high angles the spherical aberration is the limiting factor (for 100-kV microscopes, $C_S \approx 8.2$ mm and $C_C \approx 3.9$ mm). The optimum radius of least confusion is achieved for a certain β-value and the radius of confusion corresponding to that optimum is

$$\varrho_0 = 0.9\,\lambda^{3/4} C_S^{1/2} \tag{2.24}$$

Therefore, a gain in resolution can be achieved by reducing C_S and by reducing λ (i.e., using a higher voltage). At present, many microscopes used in material science and in solid-state chemistry operate at 200 – 400 kV.

At higher voltages, radiation damage to the specimen severely limits observation time. Advanced designs aim at reducing C_S to allow a decrease of the high voltage for a given resolution. Practical resolution limits are at present ca. 0.16 nm, but new developments tend to peak this value to below 0.10 nm.

Directly interpretable high-resolution images (i.e., having a direct relationship to either the projected lattice potential or the electron density) are formed by the interference between beams passing through the “window” in the image transfer function (ITF). As a result, only low-order reflections (i.e., low-order Fourier components of the lattice potential) generally contribute to the image, which limits the detail that can be resolved (irrespective of the point resolution) since fine details are carried by the high-order Fourier components. However, information transmitted beyond the window (i.e., by the rapidly oscillating part of the image transfer function) can also be used. This information can be extracted by computational techniques, for instance, by using as input a set of images made at a series of closely spaced defocus values [195].

2.2.9.4. *Image Formation Models [196]*

Fourier Model. High-resolution image formation is considered most conveniently as occurring in two steps. In the first step, electrons propagate through the crystal and produce a two-dimensional periodic electron distribution at the exit face, which images the projected lattice potential or the projected electron density. In a second step, this exit face acts as a planar distribution of point sources of spherical electron waves, which interfere behind the foil and form the diffracted beams that move in the lens system of the microscope. Interference of these beams produces the final image, which will be directly interpretable only if the beams interfere with the correct phases.

The resolution of the image depends on the spatial frequencies of the highest-order beams admitted by the selector aperture that still contribute to the image with the correct phase. Only beams passing through the window in the ITF contribute to a directly interpretable image.

The image will exhibit more detail as the order of included reflections increases, but it will give a faithful representation of the structure only if the Fourier components have correct relative phases; this puts a practical limit on the number of useful reflections.

Complete software packages for the simulation of high-resolution images are available commercially (see, e.g., [197]).

Channeling Model. An alternative model that emphasizes the particle nature of electrons provides a simple intuitive picture [198]. An atomic column parallel to the incident beam is a cylindrically symmetrical potential well, which acts on the moving incident electrons as a succession of alternating convergent and divergent lenses. At the entrance face of the foil the incident electron distribution is uniform, but in the first part of the foil the electrons are attracted toward the core of the atom columns and focusing occurs, transforming part of the potential energy of the electrons into kinetic energy. Subsequently the electrons repel one another and defocusing occurs. The focusing – defocusing motion occurs periodically as a function of the depth in the foil, the depth period being a function of the atomic number of the atoms in the column. The heavier the atoms are, the smaller is the depth period. As a result, for a foil of given thickness, one type of atom column will give rise to a relative maximum in the electron distribution, whereas another type may give rise to a relative minimum. These extremes are not necessarily imaged as extremes of the same nature. A maximum may be imaged either as a bright dot or as a dark dot, depending on the defocus and on the foil thickness (see Fig. 44). This model explains why different atom columns produce dots of different brightness. The focusing and defocusing behavior was confirmed by computer simulations, which also showed that the depth periods are in the 4 – 10-nm range depending on the atomic number.

Figure 44. Channeling of electrons along columns of atoms parallel to the incident beam

Alternating focusing and defocusing occurs. The focusing distances Δ_A and Δ_B are different for A and B columns

2.2.9.5. *Image Interpretation [196]*

Trial and Error. Digital simulation programs for HRTEM are usually based on the Fourier approach. They allow one to compute the image of a given structure projected along a given zone axis as a function of the foil thickness and of the imaging conditions (defocus) for a microscope with known characteristics (spherical aberration coefficient, accelerating voltage, beam convergence) (Fig. 45).

Figure 45. High-resolution image of the high-temperature superconductor $Y_2Ba_4Cu_7O_{15-\delta}$. The bright dots reveal the heavy atom columns as projected along two different zones. Simulated images are reproduced as insets. The projected unit cell is outlined (Courtesy G. Van Tendeloo). The images were made at optimum defocus. The two images refer to different specimens, with comparable thickness.

Identification of a structure or of a defect in a structure proceeds by “trial and error”. A model is proposed, and a matrix of images that varies the two main independent variables (foil thickness and defocus) is computed.

These theoretical images are then compared with the observed images at the different thicknesses along a wedge-shaped part of the foil. A solution is considered acceptable when the correspondence between observed and computed images is judged visually to be “good enough” for all available thicknesses at a constant defocus. This comparison allows one at the same time to estimate the foil thickness and the defocus; these quantities are usually not known a priori. Numerical criteria to quantify the goodness of fit have been proposed but have seldom been applied as yet. In recent developments, high-resolution images have been used to determine the chemical composition along individual columns in rather special circumstances, such as along the interfaces in synthetic layer structures of semiconductors grown by molecular beam epitaxy. The composition profile across an interface can be obtained at an atomic scale. The application of these methods requires a certain amount of a priori knowledge concerning the structure.

Direct Retrieval. “Direct retrieval” use as the input a series of images taken at closely spaced defocus values (focus variation method). If the microscope parameters describing the transfer function and its inverse are known, the projected wavefunction at the exit plane of the foil can be reconstructed. From this, the projected structure (the object) can be retrieved by using an analytical formulation of the channeling model. Knowing the projected structure along more than one zone axis allows one to reconstruct the three-dimensional structure. Less a priori knowledge is required than for the methods based on “trial an error”.

2.2.10. ***Scanning Transmission Microscopy [199]***

Transmission electron microscopy can also be performed with a scanning incident beam (STEM). In a STEM instrument a

fine convergent electron probe, formed by demagnifying a small, but brilliant, electron source, is scanned over the specimen area of interest. The incident beam is focused on the specimen plane and a convergent electron diffraction pattern is formed in a plane behind the specimen. Parts of this diffraction pattern (CBED pattern) can be selected by an appropriate aperture, and the signal detected hereby gives rise to an electronic signal which is displayed on a TV monitor, the scan of which is operated synchronously with the probe scan. A bright field (BF) image is obtained when the directly transmitted beam is selected. If one or several beams outside the central beam are selected, a dark field (DF) image is produced.

High resolution is achieved by making the effective probe size as small as possible. For this purpose use is made of a field emission gun with an effective source diameter on the order of 5 nm; demagnification then allows a probe size on the order of 1 nm in diameter to be obtained. The beam current is of the order of 0.5 nA.

The essential electron optics of STEM and CTEM instruments are in principle not very different, even though the electrons travel in opposite senses in the two instruments. A comparison of the principles of STEM and CTEM is represented schematically in Figure 46. In CTEM the image signal is produced in parallel (i.e., simultaneously) in all parts of the image plane (e.g., a photographic plate), whereas in STEM the signal is generated in serial form, as a time-dependent electric signal, which makes it easy to apply on-line image processing. Like in CTEM various signals, excited by the passage of the electron beam through the specimen, can be displayed by using the appropriate detectors.

Figure 46. Scanning transmission electron microscopy

2.2.11. *Z-Contrast Images [200]*

The commonly used imaging modes (CTEM, HRTEM) are based on interference and diffraction and rely strongly on coherently scattered electrons. However, simultaneously with the coherent scattering, incoherently scattered electrons also are produced by thermal diffuse scattering and in particular by Rutherford scattering. In the STEM mode these incoherently scattered electrons can be used to image atom columns, provided that the proper electron optics are available. A fine electron probe is obtained by focusing the incident convergent electron beam in the sample and scanning over the foil. Thereby, a significant fraction of the incoherently scattered electrons, emerging from the sample at relatively large scattering angles, is captured in an annular aperture and detected.

in the case of incoherent imaging conditions, the contrast transfer function is a monotonously decreasing function of the spatial frequency, whereas under coherent imaging conditions it is a rapidly oscillating function. This has important consequences. In the coherent case the brightness of a dot imaging a given atom column may change from bright to dark and vice versa as a function of defocus. In contrast, in the incoherent case, the relative brightness of a dot remains consistently the same, independent of defocus, i.e., there is no contrast reversal. Moreover, the dot brightness increases monotonously with increasing average *Z* value of the atoms in the column as a consequence of the contribution of the Rutherford scattering to the incoherently scattered electrons. Incoherent images can therefore be interpreted on an intuitive basis even for relatively large thickness. It can be shown that structure retrieval is in principle possible and simpler than in the case of coherent imaging. The method is therefore well suited to the study of geometric defects in crystals.

2.2.12. *Analytical Methods*

2.2.12.1. *X-Ray Microanalysis [150]*

Principle. An important feature of electron microscopy is the possibility of performing in the same instrument both a qualitative and a quantitative elemental analysis of the same small crystal fragment that produced the electron diffraction pattern and the image. The most commonly used method consists in principle of detecting the characteristic X-rays excited by the high-energy electrons passing through the specimen.

For this purpose, an X-ray spectrometer, mounted sideways on the microscope column at the level of the specimen holder, captures the X-rays emitted in all directions by the specimen within a certain solid angle centered around the chosen takeoff direction and transmitted through an X-ray transparent window (Fig. 47). The spectrum consists of the characteristic X-ray lines superposed on a continuous background of bremsstrahlung (see also ⟶ Surface and Thin-Film Analysis – Ultraviolet Photoelectron Spectroscopy (UPS), ⟶ Surface and Thin-Film Analysis – Auger Electron Spectroscopy (AES)).

Figure 47. Specimen – detector configuration used in X-ray microanalysis

a) Si(Li) detector; b) Mini lens; c) Liquid-nitrogen reservoir; d) X-ray window; e) Specimen; f) Objective lens; g) Crystal; h) Detector; i) Crystal spectrometer

The physical basis of X-ray microanalysis is Moseley's law [201], which establishes a direct and systematic relation

between the atomic number Z and the characteristic X-ray wavelength λ in a family of X-ray lines (e.g., associated with similar transitions in different elements):

$$\lambda = A/(Z - C)^2 \tag{2.25}$$

A and C depend on the considered family; K_α, K_β, . . . , L_α, . . . , X-ray lines are produced when an inner shell (e.g., K-shell) electron has been ejected from the atom by absorbing an amount of energy from an incident electron, exceeding the critical ionization energy associated with that shell. On deexcitation, this vacant level is filled by an electron originating from a higher-lying shell or subshell of the same atom. The transition is accompanied either by the emission of X-rays, which is the phenomenon of interest here, or by the ejection of an Auger electron (⟶ Surface and Thin-Film Analysis – X-Ray Photoelectron Spectroscopy (XPS)). Equation (2.25) shows that the atomic number can in principle be determined by measuring the characteristic X-ray wavelength.

Wavelength-Dispersive Spectrometry (WDS). Two types of X-ray spectrometers are in use: wavelength-dispersive spectrometers and energy-dispersive spectrometers.

In wavelength-dispersive spectrometers, dispersion is achieved by an analyzing crystal. Since the Bragg angle for a given set of lattice planes depends on the wavelength of the incident radiation, X-rays of different wavelengths can be separated spatially by the crystal, and a spectrum can thus be analyzed by changing the orientation of the analyzing crystal by θ and detecting the amount of radiation passing through a slit whose angular position is rotated simultaneously over 2θ. Often the analyzing crystal, which acts as a grating, is cylindrically curved so that focusing along a line occurs. The detector, usually a gas proportional counter, is placed in the focus and connected to a single channel analyzer, followed by standard counting electronics.

Depending on the wavelength range to be detected, different analyzing crystals are necessary; provision is usually made on the equipment to allow switching in several crystals from a built-in carousel. Extension of this method to long-wavelength X-rays is hampered by the absence of suitable crystals with large interplanar spacings. Synthetic layered structures, prepared by molecular beam epitaxy, and Langmuir – Blodgett layers have been used for this purpose since the end of the 1980s.

Energy-Dispersive Spectrometer (EDS). In energy-dispersive spectrometers, spectral analysis is based on measuring the X-ray energy rather than the wavelength. As a detector, a solid-state ionization chamber is used (e.g., a $p - i - n$ junction in silicon, an intrinsic germanium crystal, or a mercuric iodide crystal). The energy resolution is of the order of 150 eV or less for X-ray energies in the range 1 – 12 keV (Fig. 48). The silicon $p - i - n$ junction is produced by diffusing lithium (at elevated temperature) into a p-type silicon slab under a reverse bias, creating an intrinsic region via the exact compensation of fixed acceptors by mobile lithium donors, as a result of electromigration of the lithium ions. Under reverse bias an electric field is created in the broad intrinsic region, which acts as the sensitive volume. Such detectors must be kept permanently at liquid-nitrogen temperature since lithium ions migrate at room temperature. When an X-ray photon passes through the intrinsic region, its energy is dissipated almost entirely by the formation of electron – hole pairs, which are swept away by the reverse bias field and produce a voltage pulse across the detector crystal that is proportional to the energy of the incoming X-ray photon. The X-ray spectrum is then established by analysis of the pulse heights with a multichannel analyzer. For qualitative analysis, only the line positions are important, but for quantitative analysis the line shape and the peak heights are also used. Fundamental for the interpretation of EDS spectra is the assumption that all the energy of the X-ray photon is deposited in the detector (silicon escape peaks are ignored). The number of charges n created by a photon with energy E is then given by $n = E/E_i$, where $E_i = 3.6$ eV for silicon. Since the charge pulses to be detected are small, reducing the noise of the detector is essential; this is a second reason for cooling the detector. EDS has many advantages over WDS, the main ones being the much shorter acquisition time and the smaller minimum useful probe size. On the other hand, complications also occur that do not arise in WDS instruments; the major ones are escape peaks, pulse pileups, electron beam scattering, peak overlap, and window absorption effects. In practice, the latter prevents detection of light elements with $Z \leq 10$ (beryllium window) unless a windowless detector is used.

Figure 48. Example of X-ray spectrum obtained by means of an energy dispersive spectrometer

The material is a chromium aluminum alloy.

Quantitative Analysis. Quantitative analysis is based on the assumption that the intensity of the Lorentzian X-ray peak is proportional to the number of atoms of the species responsible for the peak. Since the theoretical relations are complicated and involve a large number of parameters, some of which are difficult to evaluate, well-characterized homogeneous standards are generally used for calibration, the composition of which has been determined by classical chemical macroscopic methods. These standards, which should also have similar shapes to the sample, are then measured in EDS equipment under the same well-defined and reproducible conditions as the unknown sample, and the spectra are compared. This calibration leads to the so-called k_i factors (coefficients of proportionality) for the different elements [202]:

$$C_{i_{\text{unknown}}}/C_{i_{\text{standard}}} = I_{i_{\text{unknown}}}/I_{i_{\text{standard}}} = k_i \tag{2.26}$$

where C_i are weight fractions.

Since k_i may depend on the particular matrices, Equation (2.26) must be corrected as follows [150, 203]:

$$C_{i_{\text{unknown}}} / C_{i_{\text{standard}}} = Z_i \times A_i \times F_i \qquad (2.27)$$

where the matrix correction factors Z_i>, A_i, and F_i still depend on the element under consideration; Z_i is the factor due to atomic number; A_i is due to X-ray absorption; and F_i to X-ray fluorescence. Other correction factors are due to the specimen geometry because X-ray production is depth dependent since it is proportional to the local electron energy. In the thin foils used in TEM the *ZAF* correction factors can often be neglected. X-ray microanalysis allows quantities of material of the order of 10^{-11} g to be analyzed; the concentration can be as low as 0.01 %, and the precision is of the order of 1 %.

For a more detailed discussion of the method and its technicalities, see [202-204].

Special Effects [205]. For foil orientations close to an exact Bragg orientation, the transmitted and scattered wave fields both propagate along the lattice planes. In a model crystal with a primitive structure, one wavefield has its maximum amplitude along planes coinciding with the atomic planes; the other has its maximum along the planes midway between atomic planes. For $s > 0$, the latter wavefield is excited, and therefore easy transmission occurs since the electrons in this wavefield avoid the atom cores (Bormann effect). For $s < 0$, the former wavefield is excited, but strongly absorbed, since the electrons pass close to the atom cores and can excite X-ray emission. X-ray emission is thus expected to be enhanced on the $s < 0$ side of a bent contour ($s = 0$).

In a crystal whose superstructure consists of alternating A and B atomic layers parallel to the considered lattice planes, which are close to the exact Bragg position, one type of wavefield is peaked along the planes of A atoms, whereas the other is peaked along the B-atom planes. Depending on the sign of *s*, one of the wavefields is enhanced relative to the other; hence the A and B atomic layers will be excited unequally. Under such conditions, X-ray microanalysis may produce erroneous results for the A/B ratio. Therefore, foil orientations should be avoided that cause an extinction contour to pass through the selected area due to anomalous transmission. On the other hand, this effect has been exploited to locate the site occupied by a third atomic species, in an AB superstructure, using a technique called ALCHEMI (atom location by channeling-enhanced microanalysis) [205].

2.2.12.2. *Electron Energy Loss Spectrometry (EELS) (* ⟶ Surface and Thin-Film Analysis – Electron Energy Loss Methods*) [206]*

Principles [150, 207]. Apart from elastic scattering, which is responsible for electron diffraction, inelastic scattering events also occur as electrons pass through the foil. Inelastic processes can be caused by (1) single electron excitations, such as X-ray and Auger electron production; and (2) collective excitations, such as volume and surface plasma oscillations (plasmons) and phonons. Collective excitation can be revealed indirectly as characteristic energy losses of the incident electrons. The energy of elementary excitations (plasmons and phonons) is low compared to the incident electron energy (100 – 140 kV).

Plasmons have energies in the range of 10 – 20 eV, whereas phonon energies are of the order of 10 meV. Individual quantized plasmons are thus much easier to detect than phonons. Since the positions of the plasmon loss peaks are characteristic of the materials, they can be used as analytical tools for aluminum and magnesium, for example.

However, for chemical analysis, the absorption edges in EELS curves are more important (Fig. 49); they reflect the absorption phenomena leading to X-ray production and exhibit a fine structure on the high-energy side. This fine structure is referred to as EXELFS (extended energy loss fine structure) [208], which is the analogue of EXAFS (extended X-ray absorption fine structure). The steep rise on the low-energy side of the absorption edge is due to the excitation of inner-shell electrons and characterizes the element.

Figure 49. Example of EELS (electron energy loss spectrometer) spectrum of TiC

On the low-energy side the plasmon peak is visible. The fine structure on the high-energy end is caused by interference of waves reflected by the neighboring atoms

The fine structure is produced by the electron wave originating from an inner shell that is partially back-reflected by the surrounding atoms, which leads to a modulation of the excitation probability of inner-shell electrons. This fine structure can therefore provide information not only on the chemical nature of the absorbing atom, but also on the number of nearest neighbors and their distance.

As an analytical tool, EELS is in a sense complementary to X-ray microanalysis and makes use of the same type of phenomena. EELS works well for light elements, whereas X-ray microanalysis is much more difficult to apply to elements with $Z \leq 11$.

Spectrometers. The simplest system uses a magnetic prism to produce spatial separation of electrons with different energies. The spectrum is scanned by means of a slit, and a phosphor coupled to a photomultiplier is used as the detection system.

One of the most advanced types of equipment is the ω electron spectrometer [209]. It consists of four magnetic prisms that bend the incident beam back to its original direction; it can be mounted on an electron microscope column behind the specimen where inelastic scattering is produced. Slits allow a certain energy range to be selected from the spectrum. The spectrometer can thus also act as a filter and can produce, e.g., zero-loss images in which the blurring due to inelastic

scattering is eliminated.

Since the 1980s *X-ray microanalysis* based on energy-dispersive spectrometers has become a routine technique. Equipment as well as data processing hardware and software are available commercially as optional accessories for most microscopes. In the late 1990s the range of applications of EELS spectroscopy was considerably expanded and extended to nanoscale samples. The commercial availability of user-friendly equipment compatible with most transmission electron microscopes has greatly stimulated its use. Also the improvements in the interpretation methods and the development of the corresponding computer software greatly contributed to the expansion of its use. It is now possible to map the spatial distribution of selected features of the information contained in the EELS spectrum. In this way spatial distribution of different elements (also light elements) can be mapped with nanometer resolution, but for instance also the spatial distribution of different ionization states of the same element can be visualized. These advances were made possible by the use of arrays of diodes that allow parallel detection instead of the initially used serial detection.

2.2.13. *Specimen Preparation*

The objective of all specimen preparation methods is to obtain a crystal fragment that is sufficiently thin to transmit electrons with energies of 100 keV or more, and has a sufficiently large lateral size. The numerous methods available depend strongly on the type of material and observation method.

2.2.13.1. *Diffraction Contrast Specimens*

Specimens should have a thickness of a few hundred nanometers. If too thick, the foil is not transparent; if too thin, achieving a two-beam orientation is difficult; moreover, the sample is not representative of bulk material for a number of applications.

Electrically conducting bulk samples (metals and alloys) can generally be thinned by electropolishing; *bulk ceramic samples* are often chemically thinned and polished. The resulting sample is usually perforated in the center; the edges of the hole are then wedge shaped and have transparent edges.

Insulating thin foils may become charged and deflect the electron beam; this can be avoided by coating the specimen with a thin layer of amorphous carbon, which is electrically conducting.

Thin films of uniform thickness can be obtained by *vapor deposition* under vacuum or by *chemical deposition* techniques; such samples usually have microstructures that are different from those of samples prepared from bulk material.

Layered crystals exhibiting a pronounced cleavage plane, such as graphite or MoS_2, can be thinned by repeated cleavage to produce rather uniformly thin specimens.

A truly universal thinning method does not yet exist. However, *ion beam bombardment under grazing incidence* is applicable to many materials, in particular to brittle ones such as most semiconductors. In the first step, these materials are mechanically polished to produce slabs with dimples; subsequent ion beam thinning under grazing incidence then produces a hole whose edges are wedge shaped. Thinning can be achieved either from one side only or from both sides of the slabs; this is important, for instance, for quantum wells grown by molecular beam epitaxy. Surface damage left after ion bombardment can often be removed by a final chemical polish. Figure 50 schematically represents thinning methods used for semiconductor specimens.

Figure 50. Preparation of a cross section of integrated circuits

2.2.13.2. *High-Resolution Specimens*

The various methods described above can also of course be used to prepare specimens for use in high-resolution imaging. However much thinner specimens (1 – 10 nm) are required than for diffraction contrast. Nevertheless, more rudimentary methods can often be used successfully, since much smaller lateral dimensions of the specimen can be tolerated. Specimens of brittle materials (e.g., oxide superconductors) are in many cases obtained simply by crushing the material in a quartz mortar under a protecting organic liquid. In such a way the crystal fragments are dispersed in a suitable liquid, and a drop of the suspension is deposited on a grid covered with a holey carbon film and allowed to dry. The edges of fragments protruding over the holes are potentially suitable specimens, but actually only a small fraction of the crystal fragments are sufficiently thin to produce high-quality images. The thickness of the specimen is often the resolution-limiting parameter. Materials that deform plastically when crushed at room temperature often behave as brittle when crushed while immersed in liquid nitrogen.

2.2.14. *Applications to Specific Materials and Problems*

The number and diversity of applications of different forms of electron microscopy have become so large that an exhaustive survey, even when restricted to chemical aspects, is almost impossible. In particular, its application to structural problems in solid-state chemistry has evolved explosively in recent years. The examples given in what follows attempt to show as large a diversity as possible.

2.2.14.1. *Crystal Structures*

Only in simple cases can an “ab initio” structural determination be made by electron microscopy and diffraction, essentially because in electron diffraction the intensity of the reflections is not simply proportional to the square of the structure amplitude, but also depends in a complicated manner on the orientation and the thickness of the sample.

However, whereas X-ray and neutron diffraction provide only average structures (⟶), electron diffraction and microscopy can provide detailed information on local structures, especially when the average structure is known from other techniques. Also planar defects (i.e., local deviations from the average structure) can be studied to suggest possible new structures in which such defects occur periodically.

Since electron microscopy requires minute samples, the crystallography of materials that are available only as small particles (e.g., catalysts) can be studied in direct and reciprocal space. The early crystallographic studies on C_{60} and C_{70} crystals were for instance, performed by electron diffraction [210]. Even fine powders or fine-grained ceramics contain single crystal particles large enough to produce a single crystal electron diffraction pattern; therefore, the lattice parameters and the unit cell can be determined easily, albeit with moderate precision. Subsequently, X-ray powder diffraction patterns can be indexed unambiguously and the lattice parameters determined with high precision. Electron diffraction and especially high-resolution electron microscopy are complementary techniques to X-ray and neutron diffraction.

Imaging Modes for Various Materials.

Polytypes, Mixed-Layer Polytypes. The structures of polytypes are usually based on the various stacking modes of closely packed layers of spheres. The stacking sequence can best be revealed by imaging the structure along the zone parallel to the direction of the close-packed rows of atoms. Figure 51 shows a foil of SiC – 15 R imaged along the close-packed rows by using three different modes; it illustrates clearly the effect on the image detail of increasing the number of beams participating in the image-forming process. In Figure 47 A, only two successive spots out of the densely populated row of 000l spots are included; only the superspacing consisting of five-layered SiC lamellae is revealed as a line image. The isolated stacking faults are imaged as anomalously wide line spacings.

Figure 51. Imaging of the 15 R polytype of SiC along the closely packed rows of atoms

A) Two successive spots of the 0001 row contribute to the image; only the five-layer lamellae are imaged as lines; singular line spacings represent stacking faults; B) Cluster of five successive spots of the 0001 row contributes to the image; single SiC layers are revealed; each lamellae of A) is seen to contain five layers; C) Spots from parallel rows are allowed to contribute to the image; the stacking sequence ABCAC can be deduced from the two-dimensional image since close-packed atom columns are imaged as dots

Including in the aperture, a cluster of at least five successive spots of the central row between the 0000 and 00015 reflections, but excluding parallel rows, reveals the individual SiC layers and the superperiod due to the five-layered lamellae as lines; it shows in particular that the superperiod contains five layers (Fig. 47).

Finally, when spots from neighboring dense rows are also collected, a two-dimensional dot pattern is obtained and the close-packed rows are imaged as bright dots; the stacking sequence ABCAC . . . is directly revealed (Fig. 47).

The same imaging mode is used for the study of mixed-layer compounds based on the epitaxy of close-packed layers [211].

Ordered Alloys. The diffraction patterns of ordered binary alloys, derived from the face-centered cubic (fcc) structure, consist of strong basic spots that would also be produced by the disordered fcc lattice, and of weaker superlattice spots characteristic of the superstructure. The first-order superlattice spots correspond to larger interplanar spacings and are thus closer to the origin than the basic spots. Therefore images can be produced by selecting superstructure spots next to the direct beam only and excluding basic spots. The image so obtained (*bright-field superlattice image*) reveals only the configuration of the minority atoms as bright dots, since these atoms determine the superlattice. This information is sufficient to determine completely the projection of the superstructure, provided the basic lattice is known.

An image can also be formed exclusively by means of the superstructure spots situated within a reciprocal unit cell of the basic lattice (*dark-field superlattice image*) [212]. This last mode produces the best-contrasted images of the minority atom sublattice (Fig. 52).

Figure 52. Dark-field superlattice image of Au_4Mn

The manganese atoms are represented as bright dots. Note the presence of two orientation variants and several translation variants [212, 214]

If basic and superlattice spots are included in the image-forming process the basic lattice is also revealed; minority and majority atoms are imaged as dots with a different brightness. Such images contain information that is redundant if only the superstructure is sought. Examples of superlattice images of ordered alloys obtained by using the bright-field superlattice mode are reproduced in Figure 53.

Figure 53. Various superstructures in ordered binary alloys imaged using the bright-field superlattice mode and compared to structural models

Long-Period Interface Modulated Structures. Many long-period structures are derived from simpler structures by the periodic introduction of planar translation interfaces. Typical examples are the long-period antiphase boundary structures in many ordering alloy systems such as Au – Mn, Cu – Au, and the shear structures derived from a simple transition-metal oxide structure such as WO_{3-x}, TiO_{2-x}. Such compounds produce characteristic diffraction patterns. In combination with their high-resolution images, their structures can usually be elucidated completely, including local deviations from the average structure, which often occur in such phases.

In a model [213], the superstructure is assumed to consist of identical slabs of basic structure with thickness *D* limited by planes normal to $\bar{e}_n$. Usually the slab thickness is equal to an integer number *n* of unit cell parameters *a* of the basic structure i.e., *D* = *na*, but this need not be the case. Successive slabs are separated by planar interfaces (stacking faults, anti-phase boundaries, discommensuration walls, etc.) with a displacement vector $\bar{R}$ and a unit normal $\bar{e}_n$.

The diffraction pattern of such a structure consists of clusters of equally spaced superstructure spots (spacing: 1/*D*), called satellites, located around the positions of the basic spots. The intensity of the satellites decreases rapidly with separation of the satellite from the basic spot to which it belongs, which also determines its position. The positions $\bar{H}$ of satellites are given by the relation [213]

$$\bar{H} = \bar{h} + (m + \bar{h} \cdot \bar{R})\, \bar{q} \qquad (2.28)$$

(*m* = integer; order of the satellite; $\bar{q} = (1/D)\bar{e}_n$. The diffraction pattern thus exhibits main (or basic) spots at $\bar{h}$. With each basic spot $\bar{h}$ a linear sequence of equidistant satellites $m\,\bar{q}$ is associated. These sequences are perpendicular to the interfaces and they are shifted with respect to the positions of the basic spot over a fraction $\bar{h} \cdot \bar{R}$ of the intersatellite spacing; $\bar{q}$ is the wave vector of the modulation. Provided the basic structure is known, the long-period structure can be determined from the geometry of the diffraction pattern.

If the displacement vector $\bar{R}$ is parallel to the interfaces, the latter are termed conservative since the long-period structure has the same chemical composition as the basic structure.

If $\bar{R}$ is not parallel to the interfaces the superstructure may have a composition different from that of the basic structure; this is the case for shear structures, in which the interfaces perpendicular to $\bar{e}_n$ are generated by removing slabs of material with thickness $\bar{R} \cdot \bar{e}_n$, followed by closing the gaps so created by the displacement $\bar{R}$. If the removed slab has a composition different from that of the basic structure, the overall composition changes in the process.

The alloy, based on a face-centered cubic lattice, with ideal composition $Au_{22}Mn_6$, produces the diffraction pattern shown in Figure 54 A and represented schematically in Figure 54 B. It consists of sequences of superstructure spots, marked as full dots in Figure 54 B, associated with the basic spots marked as small open disks in Figure 54 B, which are the spots that would be produced by the Au_4Mn structure. Both types of spots are present simultaneously in Figure 54 A because the selected sample contained a small area of Au_4Mn as well as an area exhibiting the $Au_{22}Mn_6$ structure. From the direction of the rows of superstructure spots, their spacing, and the fractional shifts, the model of Figure 54 D can be derived [214]. In this model, only the manganese columns are represented. The high-resolution image (Fig. 54 C) made in the bright-field superlattice mode can be compared directly with the model of Figure 54 D; only the minority atom columns are revealed as bright dots.

Figure 54. One-dimensional nonconservative long-period superstructure of the Au_4Mn structure, with theoretical composition $Au_{22}Mn_6$ [214]

Molecular Crystals; Fullerites. Organic crystals are usually prone to ionization damage and decompose very rapidly under electron irradiation; they can thus be studied for only a short time (a few seconds) and only with a very low electron beam intensity. Transmission electron microscopy has, therefore, seldom been applied to organic crystals. However, the all-carbon molecules C_{60}, C_{70}, etc., (fullerenes) discovered at the end of the 1980s resist electron radiation fairly well. Early structural studies on the crystalline phases of fullerenes (fullerites) were performed mainly by electron microscopy because only small quantities of sufficiently pure material were available. At room temperature, C_{60} crystals were found to have the

fcc structure, often containing intrinsic stacking faults, twins, and other defects characteristic of low stacking fault energy fcc alloys [215]. Figure 55 shows, for instance, various faults in a crystal of C_{60}: an intrinsic fault containing a dipole of stair rod dislocations in S, and a Frank partial dislocation and its associated stacking fault in A. The diffraction effects and the microstructure caused by the orientational phase transition in C_{60} at 255 K, from the room temperature fcc phase to the simple cubic low-temperature phase, were studied by means of electron microscopy [216] (Fig. 56).

Figure 55. High-resolution image of a fragment of a C_{60} molecular crystal: bright dots represent rows of C_{60} molecules

Note the presence of a stepped intrinsic stacking fault (in S). Also a Frank-type partial dislocation and its associated stacking fault are present (in A) [215]

Figure 56. Diffraction patterns of the simple cubic phase of C_{60} along a cube zone [216]

A) One variant; B) Perpendicular variant to A); C) Both variants present

Vapor-grown C_{70} crystals were found to belong to two different structural types. About 1 % of the vapor-grown crystals are hexagonally close packed; the rest are face-centered cubic. Many crystal fragments exhibit both crystal structures. The hexagonally close-packed crystals undergo several orientational phase transitions on cooling, leading to a monoclinic orientationally ordered superstructure at low temperature [217]. The fcc crystals undergo a single sluggish phase transition into a rhombohedral phase.

Quasi Crystals. Until 1984, one of the most firmly established fundaments of crystallography was the postulate that crystals have three-dimensional translation symmetry, and that only symmetry rotation axes with multiplicities 1, 2, 3, 4, and 6 can occur because they are the only ones that are consistent with homogeneous space filling. However electron microscopy and electron diffraction have shown that 5-, 8-, 10-, and 12-fold symmetry axes occur in the structure of certain, usually rapidly cooled, alloy phases with complicated compositions [218, 219]. Careful tilting experiments have demonstrated the presence of icosahedral and dodecahedral symmetry groups in many of these phases. Their electron diffraction patterns consist of sharp spots, whose geometry reflects the above-mentioned symmetry elements, but they do not exhibit translation symmetry. The same conclusions follow from high-resolution images [220].

At present, numerous alloy systems are known to exhibit noncrystallographic symmetry elements and to lack three-dimensional periodicity; they are called quasi crystals. Figure 57 shows the diffraction pattern of a quasi crystal with composition Al – Mn exhibiting a fivefold axis, whereas Figure 58 shows the corresponding high-resolution image; pentagonal arrangements of bright dots are visible in many places.

Figure 58. High-resolution electron micrograph of rapidly cooled Al – Mn alloy showing the absence of a periodic structure; pentagonal arrangements of dots can be observed (Courtesy of G. VAN TENDELOO)

Artificial Layer Structures and Semiconductor Devices. In recent years the growth of artificial layer structures, which can be used as quantum wells, has become an important research activity. The properties of such layered structures are determined to a large extent by the perfection of the interfaces, as well as the regularity of their spacing. Both parameters can be studied by means of high-resolution, cross-sectional samples. The steps in the preparation of cross-sectional samples are discussed in Section Specimen Preparation. The method is clearly destructive and cannot be used for fabrication control. However, it is the most direct way to calibrate other nondestructive methods.

Figure 59 shows a high-resolution image of a quantum well consisting of the alternation of GaAs and (GaAl)As. The positions of the interfaces are indicated by arrows. The interfaces are flat to within two or three atomic layers; no interfacial dislocations are observed. The composition profiles across such interfaces can in principle be studied by measuring the brightness of the dots representing the atom columns [221].

Figure 59. High-resolution image of quantum well consisting of alternation of pure GaAs and (GaAl)As

For the study of semiconductor devices, diffraction contrast images made in a high-voltage electron microscope (≈ 1000 kV) are often useful since thicker specimens can be tolerated than in a conventional microscope (≈ 200 kV). An example is shown in Figure 60, which is the cross section of a field effect device. The different layers have been indicated along with the orientation of the silicon substrate. The black dots numbered 1 – 5 are images of dislocations seen end on, which were nucleated by the stresses set up as a result of the oxidation process. From the spatial distribution of the dislocations the magnitude of the stress can be estimated.

Figure 60. Cross section of field effect device

The procession of dislocation 1 . . . 5 results from stresses set up by the oxidation process (Courtesy of J. VAN HELLEMONT)

During crystal growth, small oxide particles are often formed in the interior of silicon single crystals. Such particles cause a compressive stress on the surrounding matrix. This may lead to prismatic punching, whereby disks of self-interstitials limited by loops of perfect dislocations are emitted, thereby relieving the stresses. These loops can glide along cylindrical surfaces whose cross section is determined by the size and shape of the particle, and whose generators are parallel to the different glide vectors of silicon, which are of type 1/2 [110]. The geometry of the process can be established with diffraction contrast images (see Fig. 61).

Figure 61. Oxide particle in the interior of a silicon single crystal

Stresses have been relieved by prismatic punching. The dislocation loops are imaged using different reflections (Courtesy of H. BENDER)

Carbon Nanotubes, Onions. The preparation of fullerene-containing soot by the vaporization of graphite electrodes in an electric arc leads simultaneously to the formation of very fine *hollow carbon needles* or “tubules” with diameters as low as 1 nm. Electron microscopy and electron diffraction have shown that these needles consist of concentric seamless graphene tubes (2 – 15 tubes) [222]. The most remarkable feature is the helical character of some of the tubes within a tubule, as deduced from fiber diffraction patterns (Fig. 62). The helical structure is a consequence of the stepwise increase in circumference of successive concentric tubes by πc (c = lattice parameter of 2 H graphite). Since πc is not commensurate with the a-parameter of graphite the $c/2$ spacing between successive tubes and their seamless character can be reconciled only with the changing diameter if some of the tubes at least become helical. However, a detailed analysis of the fiber pattern has shown that in most tubules the majority of tubes are nonhelical [223].

Figure 62. Electron diffraction (fiber) pattern produced by a graphite nanotube showing that certain graphene tubes are helically wound, whereas others remain normal

Note the outward streaking of the diffraction spots

(Courtesy of X. F. ZHANG)

Intense “in situ” electron irradiation of particles of carbon soot for tenths of minutes in the electron microscope produces spherical particles consisting of *onion-like* concentric spherical shells of graphene-like layers [224]. The microscope allows the concentric shell structure to be imaged during its formation.

High-T_c Superconductors. High-resolution electron microscopy and electron diffraction have been applied extensively in structural studies of high-T_c oxide superconductors. In particular, $YBa_2Cu_3O_{7-\delta}$ and the related 1 – 2 – 3 family of compounds have been studied in great detail. Numerous studies of superconducting compounds can be found in *Physica*

C from 1989 onward. The generic 1 – 2 – 3 compound ($YBa_2Cu_3O_{7-\delta}$) has a structure derived from the triperovskite structure in which the succession of layers along the *c*-direction is CuO – BaO – CuO_2 – Y – CuO_2 – BaO, etc. The CuO layer consists of Cu – O – Cu – O – chains parallel to the b_0-direction; this feature breaks the tetragonal symmetry and reduces the symmetry to orthorhombic. The average structure was determined by X-ray and neutron diffraction, but several important structural features were discovered by electron microscopy. The oxygen deficiency was found to be accommodated by the absence of oxygen in a fraction of the chains in the CuO layer [225]. The structure in which one of two chains is alternately free of oxygen, the so-called 2 a_0 (or ortho II) superstructure, has an ideal composition with $\delta = 0.5$. It occurs in two orientation variants, corresponding to the (110) reflection twin texture of the 1 – 2 – 3 compound, which was also discovered by electron microscopy. The presence of the 2 a_0 structure was shown to be responsible for the 60 K plateau in the T_c versus composition curve [225]. Locally, structures with a period of 3 a_0 occur [226].

Much attention has been devoted to various substitutions in CuO layers, replacing copper ions by other metallic ions such as Fe, Co, etc., but also substituting by complex anions such as CO_3^{2-}, SO_4^{2-}, PO_4^{3-}, or NO_3^-. High-resolution electron microscopy has demonstrated that the substitution occurs in the CuO layers, and has allowed the resulting superstructures to be visualized. In the case of SO_4^{2-} substitution, for instance, the superstructure has been shown not to be commensurate with the basic 1 – 2 – 3 lattice [227]. Figure 63 shows a view along the b_0-direction of the 1 – 2 – 3 matrix. The prominent, bright dot squares reveal the SO_4^{2-}-containing rows that replace CuO chains. Their arrangement is not periodic and can best be described as resulting from a concentration wave with a wave vector that is not commensurate with the 1 – 2 – 3 lattice along the *a*-direction.

Figure 63. High-resolution image along the $[010]_0$ direction of the SO_4^{2-}-substituted 1 – 2 – $(YBa_2[Cu_{3-x}(SO_4)_x]O_{7-\delta})$ compound

The SO_4^{2-}-containing rows parallel to [010] are marked as small crosses of prominent bright dots. (Courtesy of T. KREKELS) [227]

Replacing copper by cobalt or gallium in the CuO layer results in the formation of corner-sharing chains of CoO_4 (GaO_4), tetrahedra along the [110] and [1$\bar{1}$0] directions of the 1 – 2 – 3 matrix lattice [227]. The resulting structure is still orthorhombic, but with a diagonal unit cell ($a_0 \approx b_0 \approx a_p\sqrt{2}$), where a_p is the lattice parameter of the basic perovskite. Electron microscopy [228] showed that a superstructure is formed, which is localized in the Co – O (Ga – O) layers, and in which alternating parallel CoO_4 (GaO_4) chains have mirror-related configurations, leading to doubling of the lattice parameter perpendicular to the chain direction. Figure 64 is a view of the cobalt-containing material along a $[120]_p$ direction, which allows the period doubling along a_0, as well as the possibility of polytypism along c_0, to be observed.

Figure 64. High-resolution image along the $[120]_p$ zone of the cobalt-substituted 1 – 2 – 3 compound $YBa_2Cu_2CoO_7$

Dark dots reveal indirectly the arrangement of chains of corner-sharing CoO_4 tetrahedra that replace the CuO layers. (Courtesy of T. KREKELS) [228]

Superionic Conductors. Superionic conductors often consist of a stable rigid framework forming large channels along which ions can move easily. The channels in such structures can be made visible in high-resolution images made along a zone parallel to the channel direction. Figure 65 shows such a high-resolution image of the natural mineral hollandite with idealized composition $Ba_xMn_8O_{16}$ [229]. Octagonal channels, formed by interconnected strings of edge and corner-sharing MnO_6 octahedra, are imaged as octagons of black dots. These channels are occupied by barium ions, which are also visible as black dots in the centers of the octagons.

Figure 65. Structure of natural monoclinic hollandite $Ba_xMn_8O_{16}$ as viewed along the [010] zone

The image is compared with a simulated image in the inset [229].

Polymers. Although most organic materials usually deteriorate rapidly from ionization damage in the electron beam, meaningful observations can be made on certain polymers. In Figure 66, fiber patterns of a poly(*p*-phenylene) stretched six to seven times are reproduced (PPV, an alternating copolymer of *p*-phenylene and acetylene) at two different photographic exposures to reveal the details of the pattern close to the origin [230]. The direction of stretching is indicated by arrows. The patterns of the left column (A) and (C) refer to the pristine material. On doping with $FeCl_3$ this material becomes a good electrical conductor. The effect of $FeCl_3$ doping on the diffraction pattern is shown in the right column (B and D). Whereas in the undoped material the 001 diffraction vector encloses an obtuse angle with the row of hoo

reflections, this angle becomes 90° in the doped material, which suggests that the symmetry changes from monoclinic to orthorhombic on doping.

2.2.14.2. *Defects*

Dislocations. Dislocation configurations have been studied mainly by diffraction contrast bright-field imaging since this method is very sensitive to lattice strain fields. Under these conditions, dislocations appear as dark lines when two-beam diffraction conditions close to $s \approx 0$ are used. A network of dislocations in the basal plane (0001) of zinc is visible in Figure 67.

Figure 67. Network of undissociated dislocations in the (0001) plane of zinc

Images of dissociated dislocations (i.e., dislocation ribbons) have been used extensively as a means to deduce the stacking fault energy [141].

The separation between partial dislocations is usually measured on a weak beam image (see Section Dislocation Contrast). The image, which is now a very narrow bright line on a darker background, is essentially kinematic. In the high-resolution image of Figure 68, dissociated dislocations in silicon are viewed along the [110] zone. Between the two partial dislocations an intrinsic stacking fault is present. Such configurations have been used to deduce stacking fault energies [141, 192].

Figure 68. Dissociated dislocations in silicon viewed along the [110] zone in the high-resolution mode (Courtesy of H. BENDER)

Planar Defects. The diffraction contrast images of planar interfaces that intersect the foil surfaces consist of a set of fringes parallel to the closest surface with a depth period given by $1/\sigma_g$ (which is equal to t_g for s = 0; see Section Faulted Crystals). If the planar interface is parallel to the foil surfaces, which is often the case in cleaved foils, the faulted area exhibits only a brightness difference.

High-resolution images can reveal stacking faults directly, especially in close-packed structures. In such structures the image made along a zone parallel to the close-packed rows reveals the stacking directly. A stacking fault in a wurtzite crystal is reproduced in Figure 69.

Figure 69. High-resolution image of a stacking fault in 2H-wurtzite (Courtesy of H. BENDER)

Domain boundaries and twins in planes that intersect the foil surfaces are imaged as δ-fringes (Section Faulted Crystals) [171]. The extinction condition is now $\Delta s = 0$ (or $\Delta \bar{g} = 0$!) which is satisfied for the family of planes common to the two domains. When the interfaces are nearly perpendicular to the foil plane the main effect is domain contrast (i.e., a brightness difference in the domains on either side of the interface) as shown in Figure 70, where the same twin boundaries in the high-temperature superconductor $YBa_2Cu_3O_{7-\delta}$ have been imaged in three different modes.

Figure 70. Twin boundaries in $YBa_2Cu_3O_{7-\delta}$

2.2.14.3. *Small Particles*

Like most other electron microscope techniques, transmission electron microscopy allows the particle-size distributions and particle shapes of very fine powders to be studied. Such studies are important in several areas of research: including catalysis, magnetic recording, and photography. Transmission electron microscopy provides, in addition, the possibility of obtaining electron diffraction patterns of single particles as well as high-resolution images. In Figure 71 single particles of silver vapor deposited on an amorphous carbon substrate is shown. They are clearly not single crystals but aggregates of multiply twinned fcc crystallites having an overall icosahedral shape.

Figure 71. Small silver particles consisting of an icosahedral aggregate of multiply twinned face-centered cubic crystals (Courtesy of C. GOESSENS)

The topotactic dehydration reaction [231] transforming goethite into hematite was studied “in situ” at room temperature and shown to produce small twinned hematite crystals (Fig. 72). In the initial stages of the dehydration process, satellite spots appear in the diffraction pattern around the hematite spots; they were found to be due to a texture consisting of a periodic alternation of voids and hematite crystals, rather than to a long-period superstructure.

Figure 72. Small particles of twinned hematite formed in the electron microscope as a decomposition product of goethite [231]

The crystal habit of the silver halide particles used in photographic emulsions is important since it is one of the parameters determining the photosensitivity of the film. The hexagonal and triangular (111) tabular crystals of AgCl were shown to be in fact multiply twinned on planes parallel to the habit plane. Depending on the parity of the number of twin lamellae the particle grows into either hexagonal or a triangular habit.

When silver halide crystals with a cube habit are exposed to electrons, photolytic metallic silver specks are formed “in situ” in an epitaxial relation to the silver halide substrate. This gives rise to moiré fringes parallel to the cube edges due to the difference in lattice spacing between AgCl and Ag (Fig. 73).

Figure 73. Silver chloride crystal covered by silver specks viewed along the cube zone

2.2.14.4. *Surface Studies [232]*

Crystal surfaces can be studied in a transmission electron microscope by different modes. It is possible to use an electron beam, in reflection under *grazing incidence*, magnifying the Bragg reflected beam due to planes roughly parallel to the surface. The surface of the sample must be almost parallel to the beam. The resulting image is highly distorted in the sense that the magnification in a direction perpendicular to the beam is much lower than the magnification along the projection of the electron beam. This Bragg reflection mode can be used to image surface steps and to detect surface superstructures due to reconstruction or to adsorbed layers by diffraction. A very clean vacuum is required.

A second mode consists of observing the surface profile in transmission with the *electron beam parallel to the surface*. In this way, surface relaxations and surface reconstruction can be observed together with atomic resolution of the substrate. An example of the cleavage surface of a high-T_c superconductor is reproduced in Figure 74. It allows the layer within the structure to be located along which cleavage takes place [233].

Figure 74. High-resolution image of the free cleavage surface of a superconductor ($Bi_2Sr_2Ca_1Cu_2O_x$)

Cleavage occurs between the two BiO layers [233]

2.2.14.5. *Thin Epitaxial Layers*

The development of modern miniaturized electronic devices relies heavily on the use of thin epitaxial films of which the relevant physical properties sensitively depend on their thickness and on their microstructure. In recent years high-resolution electron microscopy has extensively been applied for the primary characterization of such films. In particular various modes of accommodating the misfit between a single-crystal substrate and the epitaxial films have been discovered by this method.

Routine characterization, which necessarily has to be based on nondestructive methods can be “calibrated” by means of HRTEM, which is a destructive, but highly informative method. Examples are shown in Figure 75.

Figure 75. Thin film of $La_{1-x}Ca_xMnO_3$ on a $SrTiO_3$ (STO) single-crystal substrate

a) Plane view, low-resolution image revealing antiphase boundaries

b) High-resolution image of a cross section specimen (courtesy O. LEBEDEV)

2.2.14.6. *“In situ” Studies [234]*

By using different types of stages the specimen chamber of the microscope can be transformed into a small laboratory. Heating and cooling stages make it possible to study “in situ” the changes in crystal structure and in microtexture accompanying phase transitions, by observing (1) the appearance or disappearance of superstructure spots in the diffraction pattern, and (2) the fragmentation with translation and/or orientation domains in the direct space image.

Environmental cells can be used to study in situ solid – gas reactions, such as oxidation processes or decomposition reactions.

Plastic deformation can be studied and the dislocation propagation observed in real time in a straining stage.

The creation of radiation damage by ionization or by electron – atom collisions can be studied in medium- and high-voltage microscopes. The formation of agglomerates of point defects, such as dislocation loops and stacking fault tetrahedra, can be observed during irradiation with the image-forming electrons. (Light atoms, such as oxygen, are readily displaced by electrons of 400 kV.)

Radiation ordering and disordering in alloy systems have successfully been studied in high-voltage microscopes at different temperatures.

2.3. Scanning Electron Microscopy

2.3.1. *Introduction*

In a scanning electron microscope (SEM) [235-237], a small electron probe 1 – 10 nm in diameter scans in a raster across the surface of the specimen (Fig. 76). The incident electrons are elastically and inelastically scattered by the specimen. *Elastic scattering* results in large scattering angles and zigzag electron trajectories. Therefore, a fraction of electrons can leave the specimen as backscattered electrons (BSE) (Fig. 77). The slowing down of electrons by *inelastic scattering* results in an electron range *R*. Electrons from the specimen atoms that are excited by inelastic scattering can leave the specimen as *secondary electrons* (SE) from a thin surface layer Λ_{SE} of ca. 1 – 10 nm. By convention, electrons in the energy spectrum (Fig. 78) with $E \leq 50$ eV are called SE. The secondary electrons consist of (1) SE1 excited by the primary electrons; (2) SE2 excited by BSE on their path through the surface; (3) SE3 are excited when BSE strike the lower polepiece; or flow (4) as SE4 through the polepiece bore (see Fig. 77). The ionization of inner atomic shells results in the emission either of characteristic X-ray quanta (X) or of Auger electrons (AE).

Figure 78. Schematic energy spectrum of emitted electrons with secondary (SE), backscattered (BSE), elastically reflected (ERE), low-loss (LLE), and Auger electrons (AE)

The *image* is formed by the signal of emitted secondary electrons, backscattered electrons, Auger electrons, absorbed specimen current (SC), or X-ray quanta, which modulate the intensity of a cathode-ray tube rastered in synchronism (Fig. 76). Conventional SEMs work with electron acceleration voltages of 5 – 30 kV, whereas a *low-voltage scanning electron microscope* (LVSEM) [238, 239] uses 0.5 – 5 kV.

2.3.2. *Instrumentation*

2.3.2.1. *Electron Guns*

The following types of electron emitters are used in SEM electron guns.

Thermionic cathodes consist of a directly heated tungsten hairpin cathode at T_c = 2500 – 3000 K, or an indirectly heated pointed rod of lanthanum or cerium hexaboride (LaB_6, CeB_6) at 1400 – 2000 K. The electrons must overcome the work function Φ of 4.5 eV (W) or 2.7 eV (LaB_6) by thermal activation (Fig. 79, curve a). Between the cathode at the potential $-U$ and the grounded anode, a negatively biased Wehnelt electrode forms a crossover of diameter 20 – 50 µm (W) or 10 – 20 µm (LaB_6) as an effective electron source. The emitted electrons show an energy spread ΔE = 1 – 2 eV (W) or 0.5 – 1 eV (LaB_6). A measure of the quality of an electron gun is the axial gun brightness β:

$$\beta = j/\pi\alpha^2 \approx j_c E/\pi k T_c \qquad (2.29)$$

where j is the current density, α the aperture angle, and E the electron energy. The axial gun brightness is constant for all points on the axis regardless of lenses and aperture diaphragms (j_c and T_c are current density and temperature, respectively, at the cathode). It increases proportionally to the electron energy E, with $\beta \approx 10^5$ A cm^{-2} sr^{-1} (where sr denotes steradian) for tungsten at E = 20 keV and about ten times higher values for LaB_6.

Figure 79. Potential at the cathode – vacuum interface for W and LaB_6 thermionic emission, ZrO – W Schottky emission, and field emission guns

a) Thermionic emission; b) Schottky emission; c) Field emission

Φ = Work function; E_F = Fermi energy

Schottky emission cathodes consist of zirconium-doped tungsten tips, with a radius of about 0.5 – 1 µm, coated with a ZrO layer. This layer decreases the work function from 4.5 to 2.7 eV. A Schottky emission cathode works with a higher electric field strength at the tip that decreases the work function by $\Delta\Phi$ (Schottky effect, Fig. 79, curve b) and concentrates the emission at the tip with a virtual electron source having a diameter of 15 –20 nm. However, the electrons still have to overcome the work function by thermal activation. The energy spread is 0.3 – 1 eV.

Field-emission guns (FEG) consist of tungsten tips with a radius of ca. 0.01 – 0.1 µm. An intermediate anode at ca. 1 – 2 kV extracts electrons by tunneling through the barrier of the work function, which is w = 1 – 10 nm in width (Fig. 79, curve c). Two types of FEG exist: (1) *cold FEGs* that work with the tip at room temperature, and the tip is flashed once a

day, (2) *heated FEGs* work at 1800 K. The energy spread is only 0.2 – 0.4 eV for cold and 0.5 – 0.7 eV for heated FEGs. The gun brightness of FEGs $\beta \approx 10^7 - 10^8$ A cm^{-2} sr^{-1}.

2.3.2.2. *Electron Probe Formation*

The crossover of a thermionic gun or the virtual point sources of Schottky or field-emission guns are demagnified by two to three electromagnetic lenses (Fig. 76), so that a geometric probe size d_g is formed at the specimen with a diameter of 1 – 10 nm. A diaphragm of ca. 50 – 200 µm diameter in front of the last lens limits the electron-probe aperture α_p. The electron – probe current I_p, d_g, and α_p cannot be changed independently because of the conservation of gun brightness β in Equation (2.29):

$$I_p \approx \frac{\pi}{4} d_g^2 j_p = \frac{\pi^2}{4} \beta d_g^2 \alpha_p^2 \tag{2.30}$$

The geometric probe size d_g is superposed by aberration disks of spherical (d_s) and chromatic (d_c) aberration and diffraction (d_d):

$$d_s = 0.5 C_s \alpha_p^4; \quad d_c = C_c(\Delta E/E)\alpha_p; \quad d_d = 0.6\lambda/\alpha_p \tag{2.31}$$

with the aberration constants C_s and C_c, respectively; ΔE is the energy spread of the electron gun, and λ is the deBroglie wavelength

$$\lambda = h/mv = 1.23/\sqrt{E} \tag{2.32}$$

with λ in nanometers and E in kiloelectronvolts. An astigmatism of the last probe-forming lens can be compensated using a stigmator, which consists of magnetic quadrupoles.

The (quadratic) superposition of d_g, d_d, d_s, and d_c results in an effective probe diameter d_p (Fig. 80), where d_g and d_s dominate for high electron energies and thermionic guns, and d_d and d_c dominate for low-voltage SEM and field-emission guns. This superposition results in a minimum probe size between 1 and 10 nm at optimum apertures of tens of milliradians. An anticipated increase in resolution (decrease of electron probe diameter) requires a compensation of the chromatic aberration by using a combination of electrostatic and magnetic multipoles.

Figure 80. Double-logarithmic superposition of geometric probe size d_g for different probe currents I_p and aberration disks d_c and d_s versus the electron probe aperture α_p for a thermionic tungsten cathode

E = 20 keV; β = 7×10^4 A cm^{-2} sr^{-1}; C_s= 50 mm; C_c = 20 mm; ΔE = 1 eV

The low optimum probe aperture α_p of the SEM results in a large depth of field D_f:

$$D_f = \delta/\alpha_p = \Delta/\alpha_p M \tag{2.33}$$

where $\Delta = \delta M \approx 0.1$ mm is the resolution and M the magnification on the cathode-ray tube (CRT) screen. As a consequence, an SEM has a two-order-of-magnitude greater depth of field than a light microscope even at low magnification.

To decrease the aberration constants C_s and C_c, the focal length of the last probe-forming lens can be reduced by a stronger excitation of the magnetic lens, which means a short working distance between specimen and polepiece for high resolution. The aberration constants can be decreased further if the specimen is positioned in the lens field; this makes through-lens detection of secondary electrons necessary.

2.3.2.3. *Detectors*

Secondary electrons are most frequently used for image formation and can be detected by a scintillator – photomultiplier combination (*Everhart – Thornley detector*, Fig. 81). A large fraction of slow SE is attracted by a positively biased grid (b) and accelerated to a yttrium – aluminum – garnet (YAG) scintillator or a P47 powder scintillator (c) biased at +10 kV. The photons generated are guided in a light pipe (d) to a photomultiplier (f). This SE detector shows a high signal-to-noise ratio and a large bandwidth up to 10 MHz. The collection field of an Everhart – Thornley detector mounted on one side of the specimen can disturb the electron probe in LVSEM. In this case, beam deflection and distortion can be avoided either by a combination of electrostatic and magnetic quadrupoles forming a Wien filter, by a retarding electrostatic lens, or by through-lens detection of SE.

Figure 81. Everhart – Thornley detector for SE

a) Specimen; b) Collector grid and screen; c) Scintillator; d) Light pipe; e) Optical contact; f) Photomultiplier;

g) Photocathode; h) Dynodes; i) Anode

Backscattered electrons have enough energy for direct production of a greater number of photons in a scintillator coupled via light pipe to a photomultiplier. However, the Everhart – Thornley detector cannot be used effectively for faster BSE because only a small fraction hits the scintillator area. Therefore, *annular or semiannular top detectors* collecting BSE with a high takeoff angle or *ring detectors* with low takeoff, are applied to make the best use of the angular characteristics of BSE. Alternatively, *semiconductor detectors* can be used. The BSE produce a large number $n = E/E_i$ of electron – hole pairs, where E_i = 3.6 eV is the mean energy per excitation in silicon. These charge carriers can be separated in a *p – n* junction and form an electron beam-induced current (EBIC). BSE can also be detected by the *conversion of BSE to SE3* at the polepiece and other parts of the specimen chamber, when a negatively biased electrode around the specimen retards SE1 and SE2 from the specimen.

Detectors for LVSEM. Both scintillator and semiconductor detectors show a signal decreasing linearly with decreasing electron energy, and a threshold energy of ca. 1 – 5 keV. Therefore, their application in LVSEM requires postacceleration. As a recent alternative, *microchannel plates* (MCPS) can be used for the detection of BSE. These consist of a slice from a boule of tightly packed, fused tubes of lead-doped glass with a 10 – 20 µm inner diameter and a resistance of 10^8 – 10^9 Ω over their length. Annular disks 3 – 4 mm thick can be mounted below the polepiece. The incident electrons produce SE at the inner tube wall, which are accelerated by a continuous voltage drop along the tube with a bias of 1 keV and are multiplied inside the MCP tubes by a multiplier-like action. The anode plate and a preamplifier at a potential of 1 kV are electrically insulated by an optical decoupler or by transmitting a modulated 30-MHz signal.

2.3.3. *Electron – Specimen Interactions*

2.3.3.1. *Elastic and Inelastic Scattering*

Elastic scattering of incident electrons results from the attractive Coulomb force of the nucleus screened by the atomic electron cloud with a differential Mott cross section of

$$\frac{d\sigma_M}{d\Omega} = r(\theta)\frac{e\,Z}{4\,(4\,\pi\,\varepsilon_0)^2\,m^2\,v^4}\frac{1}{\sin^4\,(\theta/2)} \tag{2.34}$$

where $r(\theta)$ is the ratio between the Mott and Rutherford cross sections, Ω is the solid angle, Z the atomic number of the nucleus, ϵ_0 the vacuum permittivity, and m the mass of the electron [235]. The strong differences between Mott and Rutherford cross sections result from taking account of the spin – orbit coupling of electrons and solving the relativistic Dirac equation, whereas the Rutherford cross section is only a solution of the Schrödinger equation not containing the spin.

Inelastic scattering results in an excitation of electrons of the solid and a corresponding energy loss ΔE of the incident electron. Information about the differential inelastic cross section $d^2\sigma/d\Omega\, d(\Delta E)$ can be obtained from dielectric theory or experimental electron energy loss spectra (EELS; see Section Electron Energy Loss Spectrometry (EELS)) of high-energy electrons [240, 241].

A series of inelastic scattering processes with statistical energy losses results in a slowing down of electrons, which can be described by a mean energy loss per unit path length (Bethe stopping power S)

$$S = \left|\frac{dE_m}{ds}\right| = \frac{2\,\pi\,e^4\,N_A\,r\,Z}{(4\,\pi\,\varepsilon_0)^2\,A\,E}\ln\,(1.166E/J) \tag{2.35}$$

with the mean ionization potential $J \approx 12.5\,Z$. As energy decreases, fewer subshells are ionized, which can be described by a parabolic decrease of $1/S$ below $E/J = 6.3$.

2.3.3.2. *Electron Diffusion*

The decrease of mean electron energy E_m with increasing path length s of electron trajectories due to Equation (2.35) results in a mean total path (Bethe range R_B) that increases with increasing Z of the material. In low-Z material with less frequent large-angle scattering, R_B and the practical range R are equal, whereas in high-Z material with more frequent scattering, the trajectories are strongly curled and $R < R_B$, as demonstrated by Monte Carlo simulations in Figure 82. The range

$$R \approx 6.6E^{5/3} \tag{2.36}$$

is to a large extent independent of material, when R is measured in units of mass thickness (µg/cm^2) and E in keV.

Figure 82. Monte Carlo simulations of 10- and 1-keV electron trajectories in carbon and gold

A) C, 10 keV, ϱ = 1 g/cm^3; B) C, 1 keV, ϱ = 1 g/cm^3; C) Au, 10 keV; D) Au, 1 keV

2.3.3.3. *Emission of Secondary and Backscattered Electrons*

The *backscattering coefficient* η describes the fraction of *primary electrons* leaving the specimen with an energy reduced by energy losses. Emitted electrons with energies of ≤50 eV are called secondary electrons (see Section Introduction) and are described by the *secondary electron yield* δ. Both quantities depend on electron energy *E*, atomic number *Z* of the specimen, and surface tilt angle ϕ (ϕ = 0: normal incidence), and show characteristic energy and angular distributions that are important to the discussion of image formation in using BSE and SE signals.

Figure 83 shows the dependence of the *backscattering coefficient* η on atomic number *Z* for different electron energies *E*. For *E* > 5 keV, η increases monotonically with increasing atomic number. For multicomponent targets

$$\eta = \sum c_i \eta_i \tag{2.37}$$

shows a best fit to experiments, where c_i represents the mass fractions. This dependence of η on *Z* is responsible for the atomic number (compositional) contrast of the BSE signal for *E* = 5 – 30 keV (see Section Topographic and Material Contrast). The backscattering coefficient η is approximately independent of *E* in the range 10 – 100 keV. Below 5 keV, η decreases for *Z* > 30 and increases for *Z* < 30 with decreasing *E*. The reason for this is the Mott elastic cross section (Eq. 2.34). An increasing tilt angle ϕ of the specimen (ϕ = 0: normal incidence) results in an increase of η.

Figure 83. Backscattering coefficient η as a function of atomic number *Z* for different electron energies *E*

a) *E* = 5 keV; b) *E* = 4 keV; c) *E* = 3 keV; d) *E* = 2 keV; e) *E* = 1 keV; f) *E* = 0.5 keV

The *secondary electron yield* δ shows a maximum for primary energies *E* of a few hundred electron volts and decreases ~$E^{-0.8}$ for higher energies (Fig. 84). For *E* > 5 keV, the SE yield contains the contributions of SE1 excited by the primary electrons (PE) (Fig. 76) and of SE2 excited by the BSE. For *E* < 5 keV SE1 and SE2 can hardly be distinguished because the exit depths of SE and BSE have the same order of magnitude. The dependence of δ on the surface tilt angle ϕ can be approximated by $\delta \sim \sec^n \phi$, where the exponent *n* decreases from 1.3 (Be) to 1.1 (Al) and 0.65 (Au).

Figure 84. Decrease of SE yield δ with increasing electron energy *E* at normal incidence for

a) Au; b) Cu; c) C

2.3.3.4. *Specimen Charging and Damage*

Insulating specimens show a *negative charging* by adsorbed electrons, when the total electron yield $\sigma = \eta + \delta$ is less than unity beyond a critical energy E_2 where σ changes from values larger than to values smaller than unity. Therefore, a conductive coating is necessary for working at high electron energies. With decreasing energy, σ can become greater than unity below E_2. In this case, more electrons leave the specimen as SE or BSE than are absorbed. The specimens becomes *positively charged* by a few volts only because SE of low energies will be retarded. Therefore, insulating specimens can be observed at low energies without coating, although rough specimens can still show negative charging when, for example, SE cannot escape from holes.

Temperature-sensitive specimens can be damaged by *heat generation*. The increase of surface temperature at the electron probe decreases with decreasing energy, and such specimens can be observed better by LVSEM. Biological specimens are damaged by ionization, which results in a loss of mass and finally a polymerized carbon-enriched conglomerate within a layer of the order of the electron range *R*.

2.3.4. ***Image Formation and Analysis***

2.3.4.1. *Topographic and Material Contrast*

Surface topography can be imaged with the SE signal, where the contrast is generated by the dependence of δ on the tilt angle ϕ of a surface element, and by shadowing effects caused by reduced SE collection from surfaces with normals opposite to the direction of SE collection or inside holes and trenches. This results in a contrast nearly equivalent to a light illumination from the detector, which, however, is disturbed by the diffusion contrast caused by SE2 generated by BSE at a

greater distance from the electron impact. This typically results in bright zones near edges with a width of about the range *R*. Therefore, a low-voltage SEM at 1 – 5 keV decreases the diffusion effect and shows a better topography, as demonstrated in Figure 85. With in-lens operation and through-lens collection of SE by an Everhart – Thornley detector (ETD) inside the last lens, the SE signal becomes independent of azimuth, which is an advantage for the metrology of integrated circuits, but a disadvantage for recognizing the topography and distinguishing elevations and indentations, for example.

Figure 85. SE image of an etched structure (Y) on silicon with

A) 10-keV; B) 1-keV electrons

The dependence of δ and especially of η on atomic number *Z* (Fig. 83) leads to an atomic number or compositional contrast that can be used for the discrimination of phases with different mean atomic numbers, as demonstrated by an eutectic alloy shown in Figure 86.

Figure 86. Example of material contrast of an Al – Ag eutectic alloy recorded with 30-keV electrons

2.3.4.2. *Electron Channeling Effects*

Electron waves entering a single crystal propagate as Bloch waves, which results in channeling effects and an orientation dependence of all electron – specimen interactions that are concentrated at the nuclei, such as large-angle scattering for backscattering or inner-shell ionization for X-ray and Auger electron emission.

When rocking an incident electron beam, the backscattering coefficient is modulated by a few percent. This results in an electron channeling pattern (ECP) (Fig. 87) containing excess (bright) or defect (dark) Kikuchi lines (see Section Geometry of Diffraction) that are the intersections of the Kossel cones of apex 90° – θ_B and an axis normal to the lattice planes of distance *d*. Therefore, such a pattern contains the crystal symmetry, and the distances of opposite Kikuchi lines include an angle 2 θ_B, which fulfills the Bragg condition

$$2\,d\,\sin\theta_B = \lambda \tag{2.38}$$

Figure 87. Electron channeling pattern of a (111) silicon surface recorded with 20-keV electrons

Scanning a polycrystalline specimen results in changes of brightness forming the crystal orientation or channeling contrast (Fig. 88).

Figure 88. Superposed crystal orientation and magnetic contrast type I on polycrystalline cobalt

Another type of channeling pattern is the electron backscattering pattern (EBSP) in which the intensity modulation can be observed on a fluorescent screen as the dependence of backscattering on takeoff direction. An EBSP has the advantage of covering a large angular range of about ± 30°, whereas the rocking for ECP can be realized only with maximum ± 2 – 3°.

2.3.4.3. *Imaging and Measurement of Surface Potentials*

A positively biased or charged part of the specimen retards low-energy SE and appears darker than the surrounding parts at ground potential. Negatively biased or charged parts appear brighter because more SE are repelled and can reach the collection field of the ETD. This results in the voltage contrast. However, no unique relation exists between brightness and bias because the SE signal depends on the surrounding potentials (near-field effect) and the collection efficiency of an ETD (far-field effect).

For quantitative measurement of surface potentials U_s on integrated circuits, a high extraction field strength (400 – 1000 V/cm) is needed at the surface, which decreases the influence of near fields by neighboring potentials. The potential is measured by the shift in the SE spectrum after passage through a spectrometer of the retarding or deflection type [242].

2.3.4.4. *Imaging of Magnetic Fields*

Magnetic fields of the specimen can act on primary, secondary, and backscattered electrons by the Lorentz force $F = e\, v \times B$. The *magnetic contrast type 1* is caused by the deflection of SE by external magnetic fields, which can be observed for magnetic recording media and uniaxial ferromagnetic materials. The best contrast is observed when only about half of the SE are collected. Then the signal intensity can change by 1 – 10 % for opposite directions of the stray field. Figure 88 shows the superposition of magnetic contrast type 1 and the channeling contrast on a polycrystalline cobalt specimen.

Magnetic contrast type 2 is caused by the deflection of BSE in internal magnetic fields. However, sufficient contrast can be observed only for tilt angles ϕ of 40 – 50°, and the contrast increases with increasing energy, but is only a few per thousand for opposite directions of *B*. Another possibility for measuring external stray fields is the deflection of primary electrons, which pass at a short distance parallel to the surface.

2.3.4.5. *Electron-Beam Induced Current*

The mean number E/E_i of electron – hole pairs generated in semiconductors — with a mean formation energy of E_i = 3.6 eV in silicon, for example — normally recombine. The electric field inside depletion layers separates the charge carriers, and minority carriers can diffuse to the depletion layer and contribute to the charge collection I_{cc} or electron-beam induced current. Depletion layers can be formed by *p* – *n* junctions parallel or perpendicular to the surface or by Schottky barriers formed by a nonohmic evaporated metal contact. Therefore, a scanning electron probe becomes a useful tool for qualitative and quantitative analysis of junctions and semiconductor parameters [243], which is demonstrated by the following examples:

1. Imaging the position and depth of depletion layers below conductive pads and passivation layers, by utilizing the increasing penetration depth (range) with increasing electron energy
2. Measuring the width of depletion layers and their increase with increasing reverse bias
3. Imaging sites of avalanche breakdown in depletion layers
4. Imaging lattice defects (dislocations, stacking faults) and dopant striations that actively influence the diffusion length, for example, by a Cottrell atmosphere of dopant atoms
5. Measuring the diffusion length *L* from a semilogarithmic plot of the EBIC signal [~ exp (–*x*/*L*)] versus the distance *x* of the electron probe from a perpendicular *p* – *n* junction, and measuring the lifetime τ with a signal [~ exp (–*t*/ τ)] when chopping the electron beam
6. Measuring the surface recombination rate S from the variation of EBIC with increasing electron energy and depth of carrier formation

2.3.4.6. *Cathodoluminescence*

The excitation of light from materials stroked by electrons, known from fluorescent screens of TV tubes for example, is called cathodoluminescence (CL). In semiconductors with a direct band gap, electrons that are excited from the valence to the conduction band can recombine with the holes by emission of radiation, whereas semiconductors with an indirect band gap have a reduced probability of radiative recombination. In semiconductors and most inorganic materials, CL depends strongly on the concentration of dopants, which can either enhance CL by forming luminescence centers for radiative transitions or quench CL by forming centers of nonradiative transitions.

Organic specimens such as anthracene and plastic scintillator material, for example, can also show CL. Fluorescent dyes are used in biology for selective staining. However, all organic material is damaged by electron irradiation, and CL is quenched at incident charge densities a few orders of magnitude lower than those necessary for radiation damage of the crystal structure and loss of mass by ionization processes.

The CL signal can be detected by a photomultiplier or dispersively by using a spectrometer between specimen and detector. As in color TV, the signals from three detectors with color filters can be used for a real-color image [244].

2.3.4.7. *Special Imaging Methods*

The *specimen current mode* uses the current

$$I_s = I_p[1 - (\eta + \delta)] \tag{2.39}$$

to earth, which is complementary to the SE and BSE emission and can be used for imaging the compositional contrast of BSE or the magnetic contrast type 2.

In *environmental* SEM, the partial pressure of water or other gases can be increased near the specimen by differentially pumped diaphragms. This offers the possibility of observing wet specimens without drying, for example [245]. The production of ions in the gas also reduces the negative charging of the specimen by absorbed electrons in nonconductive

material.

In the *thermal-wave acoustical mode*, the electron beam is chopped at frequencies in the 100-kHz to 5-MHz range and produces periodic specimen heating. The periodic changes in thermal expansion excite an acoustic wave that can be picked up by a piezoelectric crystal transducer of lead zirconate titanate.

2.3.5. *Elemental Analysis*

2.3.5.1. *X-Ray and Auger Electron Emission*

Either ionization of an inner shell and the subsequent filling of the vacancy by an electron from higher energy states result in the emission of an X-ray quantum, or the energy is transferred to another electron in the higher shell, which leaves the atom as an Auger electron (see also ⟶ Surface and Thin-Film Analysis – X-Ray Photoelectron Spectroscopy (XPS)). The sum of the X-ray fluorescence yield ω and the Auger electron yield is unity, and ω decreases strongly from near unity to low values with decreasing Z and increasing X-ray series n = K, L, M. The X-ray quantum energies of a series increases approximately $\sim \sqrt{Z}$(Moseley's law), which is basic for elemental analysis by X-rays.

2.3.5.2. *X-Ray Spectrometers*

Two different types of X-ray spectrometer exist: wavelength- and energy-dispersive spectrometers (WDS and EDS, see Section X-Ray Microanalysis), which can be used in either an X-ray microanalyzer (XRMA) or an SEM.

A *wavelength-dispersive spectrometer* can analyze the characteristic lines of all elements down to beryllium when special analyzing crystals with a large lattice-plane spacing are used for Bragg reflection. XRMA with electron energies between 10 and 60 keV can work with WDS for recording three different wavelengths simultaneously, whereas only one WDS is used in an SEM.

The electron – hole pairs produced in the *energy-dispersive spectrometer* are separated by a voltage drop of ca. 1 kV at the crystal and result in a charge pulse proportional to the X-ray quantum energy. This pulse is amplified by a charge-sensitive preamplifier and runs through a unit for pulse shaping so that it can be recorded in a multichannel analyzer (MCA). The number of counts in a channel that is proportional to the quantum energy is increased by one unit. This allows all quantum energies to be recorded simultaneously, and the growth of a spectrum can be followed on the screen of the MCA (Fig. 89). Therefore, EDS are often also used in XRMA to survey the emitted X-ray spectrum. The vacuum inside an EDS can be separated from the vacuum of the microscope by a 8 – 10-µm-thick beryllium foil, which absorbs the characteristic radiation of elements $Z \leq 11$ below E_x = 1 keV. An organic foil or a windowless detector can also be used to record the lines of carbon (E_x = 250 eV), oxygen, and nitrogen, for example.

Figure 89. Energy-dispersive X-ray spectrum of InAs (logarithmic scale of counts per channel) recorded by excitation with 30-keV electrons (E) and X-ray fluorescence (X) using the molybdenum K radiation excited in a molybdenum foil target in front of the specimen

WDS and EDS show the following characteristic differences. *WDS* requires very accurate orientation of the electron impact on the Rowland circle within an area a few micrometers in diameter. The specimen must be planar and is shifted mechanically to record a line scan or elemental map. The electron probe can, by contrast, be scanned over an area of a few millimeters without any loss of efficiency when an EDS is used. WDS analyze only one line with a resolution of about 10 eV. The proportional counter allows a high counting rate of about 10 000 counts per second (cps). Therefore, high probe currents and a large number of counts per unit time can be recorded. The energy resolution of an *EDS* is only about 100 – 200 eV, and a ten times greater fraction of the continuum below the characteristic X-ray peaks is counted compared to WDS. This decreases the signal-to-background ratio in EDS. The poorer resolution of an EDS can also result in an overlap of neighboring X-ray lines, whereas all lines can normally be separated by a WDS. An EDS must work with lower probe currents because all quanta are counted and only a count rate of ca. 10 000 cps guarantees no overlap of sequential pulses. Pulse-rejection electronics are used when the time between two pulses is shorter than the pulse-shaping time necessary for the MCA.

2.3.5.3. *X-Ray Microanalysis*

For a quantitative XRMA [246], the number n_a of counted characteristic X-ray quanta of an element a of concentration c_a in an alloy or compound is compared with the number n_s from a pure elemental standard (c_s = 1) or a compound of known composition. Only an approximate value for c_a can be obtained from the k ratio

$$k = n_a/n_s \approx c_a/c_s \tag{2.40}$$

The exact measurement of concentration needs a *ZAF correction method* (see Quantitative Analysis.). This considers the differences in the stopping power and the backscattering of electrons between specimen and standard (*Z correction*), in the depth distribution of X-ray generation and *absorption* (*A*) of X-rays recorded under a takeoff angle of 40 – 60°, and in the excitation of X-ray quanta of the element of interest by characteristic X-rays and continuum of the matrix (*fluorescence F*).

Special correction programs must be used, for example, for tilted specimens, thin film coatings, small particles, and biological specimens.

2.3.5.4. *Special X-Ray Techniques*

When the specimen is scanned in a raster or along a line, the pulses of selected characteristic X-ray lines can produce an elemental distribution profile or map, respectively.

In a *single crystal*, the excited X-rays are Bragg diffracted at the lattice plane, and their isotropic angular characteristics show defect and excess Kossel lines of apex angle 90° – θ_B, which can be used for accurate measurement of lattice parameters and strains when the Kossel pattern is recorded on a photographic emulsion.

X-ray fluorescence analysis can be applied in an SEM when generating X-rays in a thin foil, which stops the electrons, but the transmitted X-rays can excite X-ray fluorescence in the specimen, which is recorded by an energy-dispersive spectrometer. The background of the spectrum is much lower than that from direct electron excitation (Fig. 89, curve X versus curve E), which results in a better signal-to-background ratio for trace elements. However, only larger areas 0.1 – 1 mm in diameter can be analyzed.

The small source of X-rays generated by an electron probe on a bulk target can also be used for X-ray projection microscopy.

1. The Science of Rheology

For basics of rheology, see also →Fluid Mechanics; →Plastics, General Survey; →Plastics, Properties and Testing.

1.1. Introduction

Rheology is defined as the science of deformation and flow of matter in response to the application of mechanical force. The etymology of the word emphasizes flow (Greek, $\varrho\varepsilon\omega$ and $\lambda o\gamma o\sigma$ mean "to flow" and "word," respectively). Although rheology overlaps classical (solid) mechanics at one end of its range and fluid mechanics at the other, it generally includes materials that show both deformation and flow under the influence of mechanical force. This excludes chemically cross-linked materials such as rubber, which may exhibit flow because of chemical degradation resulting from heat generated by the application of excessive mechanical force (thermomechanical degradation). However, it includes materials such as solid emulsion paints or thermoplastic polymers, which become liquid under the influence of stress and increased temperature, respectively. Many of these materials exhibit viscoelasticity; i.e., both irreversible (energy dissipative processes, viscous flow) and reversible (energy storage processes, elasticity) changes. Energy is dissipated mainly in the form of heat or sound, and stored as potential energy by conversion from kinetic energy. The exact balance between irreversible and reversible processes when force is applied to the substance and deformation results, depends on factors such as temperature and the magnitude of the force or deformation applied. It also depends on the time scale of the laboratory experiment relative to the characteristic times of internal material processes (e.g., molecular or particle diffusion). Some materials exhibit plastic flow, which is different in character from viscous flow but still irreversible (energy dissipative).

The science of rheology can be said to have been founded with the meeting of an international scientific committee on April 29, 1929 to draw up a constitution for the first society of rheology. Although the systematic study of rheology dates from then, SCOTT-BLAIR [15] has pointed out a number of rheological observations dating back to very ancient times (ca. 1650 B.C.) with the use of water clocks by ancient Egyptians (a forerunner of modern flow cups for measuring viscosity).

In 1660, ROBERT HOOKE discovered the law governing (linear) elastic deformation. In 1687, NEWTON proposed his law relating stress to velocity gradients in fluids. With these two laws, the modern era of rheology began, with substantial contributions over the next 200 years from (among others) EULER, CAUCHY, COULOMB, POISEUILLE, HAGEN, COUETTE, REYNOLDS, and BINGHAM, before the foundation of the first society of rheology in 1929 in the United States.

Because of the wide range of materials and physical concepts involved, rheology is a truly interdisciplinary science. Thus it unites contributions from mathematics, physics, and chemistry, and from specialists in colloid science, materials science, polymers, chemical engineering, and computer modeling.

1.2. Terminology

1.2.1. Rheological Measurement Terms

The two main modes of deformation, or ways in which materials can be changed in shape by the application of force, are stretching (or *extensional deformation*) and *shearing deformation*. These modes can be divided further. For example, extensional deformation can be *uniaxial*, (i.e., stretching in one direction only, as in stretching a thread or filament of material from end to end) or *biaxial* (i.e., stretching simultaneously in two directions, as in inflating a rubber balloon). Shear deformation can be *simple* or *torsional*.

In *torsional deformation*, the shear is rotational around a central axis. *Simple shear deformation* is shown in Figure 1. The upper plate can move parallel to the lower fixed plate under the influence of an applied force F. A thin slice of material of constant thickness h is trapped between the two plates and adheres to both (i.e., no slip occurs as the upper plate moves). The area of the upper plate is A. The *shear stress* σ (sometimes written as τ, which usually denotes relaxation time) is defined as force per unit area (i.e., F/A, measured in pascals). If the material is a *perfect* (or ideal) *elastic solid*, it obeys Hooke's law and is referred to as a *Hookean solid* or body. When force is applied, the upper plate moves a certain distance b, then stops in the new position for as long as the force is applied. The amount of deformation is defined as b/h (providing the angle Θ is small) and is known as the *shear strain* γ. Since the material thickness h remains constant, then according to Hooke's law, the shear strain is proportional to the shear stress applied. The constant of proportionality is the *shear modulus* of *elasticity* G. The unit of G is again pascal because the shear strain is dimensionless. Thus $G = \sigma/\gamma$.

Figure 1. Diagram of simple shear to show basic rheological parameters

If the stress is removed, the upper plate returns immediately to its original position and the mechanical energy stored as potential energy in the stretched material during application of the force is recovered in the kinetic energy of the return movement.

If the slice of the material is a simple *ideal liquid*, it obeys Newton's law and is referred to as a *Newtonian liquid*. When force is applied, the upper plate moves at a constant velocity v for as long as the force is applied. In an analogous fashion, a *shear strain rate*, usually known as the *shear rate*, is defined as v/h (denoted by $\dot{\gamma}$, i.e., $d\gamma/dt$). [Shear rate is sometimes symbolized as

D, but $\dot{\gamma}$ is used to avoid confusion with the Deborah number (see Section 1.2.2) or the differential operator d/dt, which are sometimes written as D.] In Figure 1, the liquid velocity is assumed to decrease linearly across the gap between the moving upper and the fixed lower plates. The shear rate is proportional to the stress, and the constant of proportionality is the *shear viscosity* η in units of pascal seconds (Pa · s). If the force is removed, the plate stops moving (unless the inertia due to its mass continues its motion for a short time) but does not return to its initial position. There are no stretched elements in the material that, by relaxing, can pull the plate back toward its original position, and the potential energy of the plate is zero. The mechanical energy applied has been dissipated as heat [16].

Analogously, an *elongation strain* ε and *strain rate* $\dot{\varepsilon}$, as well as an elongation modulus (*Youngs's modulus*, E) and an *elongation viscosity* $\bar{\eta}$, may be defined. Under certain well-defined material conditions, the elongation modulus is three times the shear modulus, and the elongation viscosity three times the shear viscosity (Trouton's law or ratio [17] →Fluid Mechanics, Chap. 4.3.4.).

1.2.2. Rheological Classification of Materials

Many materials show characteristics of both ideal solids and viscous liquids: they are *viscoelastic solids* or *liquids* depending on which material characteristic predominates. If the modulus or viscosity is independent of strain or strain rate, respectively (i.e., the materials obey Hooke's or Newton's laws), they are referred to as *linear* materials because their response to deformation is linear. In practice, most materials obey these laws over limited ranges of stress, strain, or strain rate. When the modulus becomes a function of strain and the viscosity a function of strain rate (usually, in both cases a decreasing function) the material response is *nonlinear*. At high shear rates, nonlinear responses can lead to so-called normal forces. These arise because the force exerted by the moving liquids becomes more and more out of alignment with the flow as the shear flow increases (see Section 2.5.5).

Most materials, even if linear, do not respond instantaneously to the application of a force; even if these materials are linear, they show a *time-dependent* response. This time dependence becomes much more obvious if the applied stress or strain itself varies with time, for example, in *oscillatory or dynamic* experiments where the variation is sinusoidal, or in transient experiments where the time scale of the material response is long compared to those of experimental artifacts. Whether a predominantly elastic or viscous response is obtained is often dictated by the relationship between the material response time (material characteristic time) and the time scale of the experimental observation. This time ratio is the Deborah number D, named by M. Reiner after the Hebrew prophetess Deborah who sang "the mountains flowed before the Lord" (Judg. 5) [18]. Low Deborah numbers indicate viscous, and high numbers (>1) elastic response [19]. Thus, even simple liquids can exhibit elasticity at very high frequencies [20].

Figure 2. Viscosity – shear rate profile (pseudoplastic)

A number of qualitative, classificatory terms are used in rheology to describe various types of material response. If the shear rate is increased linearly with time between zero and a maximum value and then decreased over the same range the resulting viscosity – shear rate plots for the increasing and decreasing shear rate halves of the experiment may either be superimposed on each other (*pseudoplastic behavior*, Fig. 2), or the plot of increasing shear rate may be above the plot of decreasing shear rate, to form a hysteresis loop (*thixotropic behavior*, Fig. 3) (see also →Fluid Mechanics, Chap. 4.1.2., →Fluid Mechanics, Chap. 4.1.3.). Instead of continuous shear rate variation, with modern rheometers a series of measurements can often be pro-

grammed at discrete shear rate values (ascending and descending as before), with a predetermined time at each value of shear rate before the viscosity is measured. Whether pseudoplastic or thixotropic behavior is observed depends on the ratio of the time the material requires to reach a steady state to the experimental time at each shear rate.

Figure 3. Viscosity – shear rate profile (thixotropy)
a) Increasing shear rate; b) Decreasing shear rate

Figure 4. Viscosity – shear rate profile with Newtonian plateaus
a) Lower Newtonian plateau; b) Upper Newtonian plateau

At both low and high shear rates, materials may show regions of Newtonian behavior, with pseudoplastic behavior at intermediate shear rate values (Fig. 4). These regions are the *lower Newtonian* and *upper Newtonian plateau regions*, respectively. The terms lower and upper refer to the shear rate values and not to the Newtonian viscosity values in each region.

Many familiar materials, such as emulsion paints, toothpaste, and cream, exhibit structure at rest (i.e., they have a more or less solid appearance). However, when sheared by stirring they become liquid-like. Although they may not show thixotropy at moderate to high shear rates, they nearly always do at low shear rates. In addition, the viscosity appears to increase more and more rapidly as lower and lower shear rates are used, with no sign of the approach of a lower Newtonian plateau region (Fig. 5). A linear plot of shear stress versus shear rate appears to extrapolate not to the origin but to a positive value of shear stress, the so-called *yield stress* [21]. Experimentally, determination of the yield stress is difficult because of the long times most of these materials require to reach a steady shear stress value at very low shear rates, problems of data extrapolation, and instrumental difficulties, etc. These materials nearly always show an upper Newtonian region because shearing breaks down the structure formed at rest and the material flows like a "normal" liquid. Other materials have different behavior at high shear rates: in particular, the viscosity increases with increasing shear rate. This behavior is referred to as (→ Fluid Mechanics, Chap. 4.1.3.):

1) *Shear thickening*, when the increase is due to enhanced flocculation of particles in dispersion (orthokinetic flocculation) [22]
2) *Rheopexy*, when the shear flow orients anisotropic particles in dispersion into favorable positions for flocculation [23]; it is usually time dependent

These phenomena have also been observed in polymer solutions and other materials, but they are associated predominantly with the rheological behavior of dispersions. Flocculation refers to the formation of clusters, chains, or networks of particles due to net attractive forces existing between the particles of dispersions. Such flocculation may also lead to the shear thinning phenomena already discussed [24], [25].

Figure 5. Viscosity – shear rate profile of a structured liquid

Other terms refer to the approximate or exact conformation of the rheological data to a particular mathematical equation, empirical equation, or theoretical model. Thus, if rheological parameters exhibit a linear dependence on frequency or shear rate on double logarithmic plots, the rheological behavior is referred to as *power law behavior*. If the material shows a yield stress and the square root of the measured viscosity (the so-called apparent viscosity) is proportional to the square root of the shear rate, the material is described as having Casson flow behavior, after the theoretical model of structure breakdown developed by Casson (see also →Fluid Mechanics, Chap. 4.1.) [26].

Finally, *reduced viscosity values* are often used. Two kinds of reduced viscosities exist. Firstly, Newtonian plateau viscosity values for *dispersions or polymer solutions* are often divided by the viscosity of the dispersion medium or the solvent, respectively, before the viscosity is related to disperse phase volume or polymer concentration. Secondly, in describing *shear rate dependence*, certain equations such as the Cross equation use a reduced viscosity of the kind

$$\frac{\eta_a - \eta_x}{\eta_o - \eta_x}$$

where η_a is the measured or apparent viscosity, and η_o, and η_x are, respectively, the lower and upper Newtonian plateau values of the viscosity.

A full glossary of rheological terms based on the 1975 British Standard [27] and the U.S. Society of Rheology recommendations [28] is found in [29].

1.2.3. Classification of Rheological Experiments and Measuring Systems

In addition to the simple type of shear deformation described (Fig. 1), two other types are also of considerable importance. These are (1) *pipe, capillary,* or *Poiseuille flow* and (2) *torsional flow*. Capillary flow in so-called *U-tube viscometers* forms the ultimate measurement standard for Newtonian liquids. The flow is characterized by a nonlinear velocity distribution across the tube radius. Further, this distribution depends on the rheology of the test liquid. Since the velocity distribution can be predicted accurately for Newtonian and for a few (mathematically) simple non-Newtonian liquids (e.g., power law fluids), U-tube viscometers are used primarily for Newtonian liquids and for very high shear rate measurements (where liquids tend to be Newtonian, anyway). Since fresh unsheared liquid is passing through the tube continuously, fewer problems occur because of errors due to mechanical energy dissipation as heat at high shear rates than in the case of the small static sample volumes used in other types of shearing deformation.

Simple deformation is really not very practicable for steady shearing measurements, because of the limitation in total strain (or the product of shear rate and time) that may be applied (one plate sliding over another with the material confined between) and the difficulties of confining all but the most viscous liquids in the gap between the plates. A simple way of reducing these difficulties is to use circular plates with a rotational movement around a central axis, instead of a sliding motion between two parallel plates; this is referred to as *torsional shear deformation* or flow. Again, one plate is fixed and the other moves with the gap between them kept constant. This measuring geometry is known as *parallel plate* geometry. However, the angular velocity of the moving plate now varies across the plate radius (zero at the center and maximum at the edge of the plate); consequently, the shear rate does also. By substituting, for one plate, a cone whose tip touches the other plate, the shear rate becomes independent of the radial distance from the center of the moving

plate. This occurs because the angular velocity increases linearly with distance from the center of the moving plate, but so does the gap between the plates (Fig. 6). This type of measuring geometry is known as *cone and plate geometry*. In practice, a small part of the cone tip is cut off or truncated (see Section 2.2.2.2). Another torsional measuring geometry is the so-called *Couette*, *concentric cylinder,* or *cup and bob*, where the material to be measured is confined in the space between the cup and a cylindrical bob inside it. By keeping the radii of the cups large and the gap between the cylinder inner wall and the bob wall small, the difference in radial velocities at the two walls is small. Consequently, the shear rate across the gap is fairly uniform (see Fig. 7), although not as uniform as in the cone and plate geometry. However, large errors may arise from the contribution of the flow between the bob end and the cup wall. Cone angles, as well as the radius of cone or plate and the radii of Couette components, can be used to control the shear range within given limits of rotation speeds.

Figure 6. Cone and plate geometry
a) Cone; b) Plate; c) Gap; d) Truncated cone tip; e) Cone angle

By rotating one member of the measurement geometry at a given speed, viscosity – shear rate measurements can be obtained. If the time scales are correct (see Section 1.2.2), *steady-state* measurements are obtained. By oscillating one member between limits at a controlled amplitude and frequency, particularly with a sinusoidal relationship to time, *oscillatory* or *dynamic* measurements are performed. Other time dependences, such as square wave or triangular, can also be applied. They are generally more difficult to use, from the point of view of both instrumental capability and mathematical analysis. An *impulsive* or *transient measurement* is made by applying a single square wave input or a linearly or logarithmically increasing input of known level for a certain period of time and measuring the material response as a function of time (see Section 2.5.3).

In *extensional flow*, the measuring geometry and test method depend on the shear viscosity and cohesive strength of the liquid. Thus, for liquids with high shear viscosity and high cohesive strength such as polymer melts, threads can be formed that can be stretched or wound on reels under well-defined conditions. More solid-like melts can be made into sheets for biaxial deformation and into bars or rods for uniaxial deformation. As the shear viscosity is reduced, a thread of liquid can be drawn into a tube from the surface of a liquid sample, and a stable liquid profile can be maintained in this manner. The thread or column can then be stretched by moving the tube vertically away from the liquid surface. However, the presence of a disperse phase, such as solid particles of filler or pigment, or gas bubbles (e.g., air), reduces the cohesive strength of the liquid and leads to instability or breakdown of the liquid column. Further reduction of the shear viscosity will render the formation of liquid columms or threads impossible, because of the very low cohesive strength of liquid threads. However, many low-concentration, high molar mass polymer solutions have extensional viscosities many orders of magnitude greater than their very low shear viscosity of a few millipascal-seconds [30]. Such liquids can be measured by the opposing jet apparatus (commercially available), by the four-roller technique (if the liquid is transparent), or in a semiquantitative manner by pressurized flow cups or thread formation as drops break away from a syringe needle tip (see Section 2.4).

1.3. Examples of Rheological Behavior

(→Fluid Mechanics)

1.3.1. Newtonian Liquids

The results of oscillatory and creep measurements for a Newtonian oil are given in Figures 8 and 9. In Figure 8, the real and imaginary components (G' and G'') of the complex modulus $G*$, as well as the dynamic viscosity η' are plotted as a function of frequency. At low frequencies the dynamic viscosity is equal in value to the (Newtonian) steady rate shear viscosity

Figure 7. Shear rate distribution in Couette geometry
A) Narrow gap, linear variation of shear rate across gap; B) Wide gap, nonlinear variation of shear rate across gap

value. Correspondingly, the imaginary component of the modulus or *loss modulus* G'' is proportional to frequency f and is much greater in value than the real component or *dynamic elasticity modulus* G'. This is typical of the dynamic response of a liquid. The loss modulus represents the portion of the total mechanical energy, supplied during the applied strain cycle, which is dissipated as heat during the cycle. The portion stored as potential energy by elastic deformation of the material is represented by the modulus of elasticity G'. The ratio of the imaginary to the real component of the (complex) modulus of elasticity yields the value of tan δ, where δ is the phase angle difference between the applied stress or strain cycle and the corresponding response (measured) cycle. The modulus of elasticity is very small at low frequencies but increases sharply (to the second power) with increasing frequency. This means that at higher frequencies, the two plots cross and the apparently Newtonian liquid becomes elastic at ca. 40 Hz. Correspondingly, the dynamic viscosity η' decreases as the high-frequency end is approached. Since simple liquids exhibit elasticity only at very high frequencies [20], many orders of magnitude above the ones shown in Figure 8, clearly another source of energy storage exists. This additional source is the measuring system itself, particularly the contribution to the overall response signal from its inertia and elasticity. This contribution becomes a maximum at the so-called natural frequency, which is close to 40 Hz for the particular measuring systems used here. The inertia term increases with the second power of the frequency. If this inertia contribution is subtracted, the elasticity modulus G' is low and virtually independent of frequency. Thus, measurement conditions should be chosen so as to eliminate or minimize the contribution of the measurement system either by appropriate corrections or by replicate measurements using different measurement systems or conditions. It is most important to have access to raw measured data values so that such corrections can be made by the operator and to understand exactly how printed rheological parameters are derived from such data in the computer software of commercial rheometers.

Figure 8. Oscillatory data (Newtonian liquids)
a) Delta; b) Loss modulus G''; c) Dynamic viscosity η'; d) Dynamic modulus of elasticity G'

Figure 9. Creep data (Newtonian liquids)
a) Retardation period; b) Relaxation period

Results for creep measurements on the same oil are shown in Figure 9. The creep experiment is a typical transient experiment in which a constant stress is applied virtually instantaneously to the samples and the corresponding strain induced in the sample is measured as a function of time (*retardation period*). The stress is then removed instantaneously, and the sample strain is again measured as a function of time during its recovery from stress application (*relaxation period*). In the case of a Newtonian oil, the strain increases linearly with time during the retardation period. However, during the relaxation period, the strain remains constant.

When the stress is removed, all the mechanical potential energy supplied during the retardation period has dissipated. Consequently, the sample remains at the maximum strain value attained during the retardation period, and no change occurs during the relaxation period measurements.

1.3.2. Elastic Solids

As an example of an elastic solid, Figure 10 and Figure 11 show the results of oscillatory (dynamic) and transient (creep) experiments on a 6 % (food) gelatin gel in water at 25 °C. The dynamic data show two striking features: first, the dynamic modulus of elasticity G' (curve a) is independent of frequency, and second, it is much greater than the loss modulus G'' (curve b). The loss modulus G'' exhibits a minimum but very little frequency dependence. The creep experiment (Fig. 11) shows an almost constant strain value during the retardation period, with almost complete and instantaneous recovery to zero strain during the relaxation period. In the figure compliance (measured strain divided by applied stress) is plotted against time. In creep experiments, it is more convenient to use compliance instead of modulus of elasticity. Compliance is denoted by J and related reciprocally to G, i.e., the unit of compliance is Pa^{-1}. Deviations from ideal Hookean behavior can be attributed to either slight irreversible deformation or, more likely, some failure in instrumental or measurement conditions.

1.3.3. Simple Viscoelastic Liquids

The 0.1 mol/L cetyltrimethylammonium bromide (1 : 1 molar ratio) – salicylic acid solution (CTAS) system in water forms long rod-like micelles that like many other such materials, exhibit strong elasticity while flowing easily like a liquid [31]. The 0.1 mol/L CTAS system is fairly unique because it exhibits virtually ideal behavior, in that it has a single relaxation time and can be modeled by the simple Maxwell model (→Plastics, Properties and Testing) [32].

As can be shown from viscosity – shear rate measurements, the viscosity is Newtonian at low shear rate values (i.e., it has little or no de-

pendence on shear rate). At higher shear rates, the viscosity decreases rapidly with increasing shear rate. At even higher shear rates the viscosity once again approaches Newtonian behavior (see Fig. 4). To display the full rheological profile of a given sample, data from more than one measurement system must often be combined, as has been done for the concentrated poly(methyl methacrylate) dispersion in the hydrocarbon system shown in Figure 12. Misalignment of data, as shown in this example, can arise from small calibration errors, difficulties in obtaining repeatable samples, or sample handling.

Figure 13 shows oscillatory data for the 0.1 mol/L CTAS system. Now the features of both the Newtonian liquid and the Hookean solid are combined, with a narrow transition region between them in the middle of the frequency range. At low frequency, the dynamic viscosity η' is constant and the loss modulus G'' is greater than the dynamic modulus of elasticity G' (predominantly viscous response). The loss modulus and the modulus of elasticity increase approximately linearly, and to the second power, respectively, with increasing frequency. At the high-frequency end, the response is predominantly elastic. The dynamic modulus of elasticity is approximately constant, and the loss modulus lies below it and decreases rapidly (as does dynamic viscosity). In the narrow frequency region in between, the loss modulus passes through a sharp maximum, at which frequency (the *crossover frequency*) the modulus of elasticity equals the loss modulus and has a value approximately half that of its maximum at higher frequencies. This crossover frequency corresponds to the *relaxation time* (the reciprocal of the frequency divided by 2π). In Figure 13, the relaxation time is several seconds. This finite relaxation time can be demonstrated even more clearly by the (transient) stress relaxation experiment. Here, a sudden strain is applied to the sample, and the resultant torque (stress) exerted by the sample is measured as a function of time. After electronic smoothing, the stress – time curve shows an initial time-independent value (corresponding to the high-frequency modulus G' value of Fig. 13) and then decreases fairly rapidly toward zero (Fig. 14). The inflection point of the plot G' versus time (curve b) corresponds to the relaxation time. This can be seen more clearly if the first differential of the curve is plotted against time (curve c, relaxation spectrum in Fig. 14). The time corresponding to the peak of this curve is the relaxation time. With identical samples and test conditions (not the case in Figs. 13 and 14), the two methods should agree fairly closely for the relaxation times.

Figure 12. Viscosity – shear rate data [concentrated poly(methyl methacrylate) dispersion]
□ and ◇ denote data obtained with different equipment

Figure 13. Oscillatory data (0.1 mol/L CTAS)
a) Dynamic modulus of elasticity G'; b) Loss modulus G''; c) Dynamic viscosity η'; d) Delta

The reason for the necessary electronic smoothing of the relaxation data in Figure 14 is that the elasticity of the sample causes a sudden twisting force (torque) to be applied to the calibrated bar of the measuring system. The system then oscillates at its natural frequency in the same way a pendulum does when moved from its position and released. Like the pendulum, this

initial oscillation decays at a rate dependent on the velocity of the dissipation of the kinetic energy of movement by the surrounding medium. In the case of the measuring system it decays rapidly because of the sample viscosity. The initial peak in the spectrum (curve c) at ca. 20 ms represents this initial decay due to the measuring system.

1.3.4. Complex Viscoelastic Liquids

In Figure 15, the results of dynamic (oscillating) measurements on a more complex system are depicted. The system measured here is a concentrated dispersion of poly(methyl methacrylate) (PMMA) in a paraffin. The dispersion is sterically stabilized with poly(hydroxystearic acid) (PHS) – PMMA graft copolymers (for preparation details, see [33]). Now a much broader transition between liquid-like viscous response and solid-like elastic response is obtained. In particular, the peak in the loss modulus G'' plot becomes very shallow, and the crossover of the loss and elasticity modulus plots occurs lower than the peak frequency. The crossover frequency now corresponds to the longest relaxation time of the system, and the broader transition is due to a range of relaxation times in the system. This contrasts with the simple system in Figure 13, where only one relaxation time occurs. By superimposing many simple systems like that of Figure 13 – each with its own relaxation time and appropriately weighted low-frequency plateau viscosity and high-frequency plateau elasticity values – the broader, less definite transition behavior shown in Figure 15 is obtained. However, as Figure 12 shows, the system is still strongly pseudoplastic under continuous shear, with a well-developed lower Newtonian viscosity and the approach of an upper Newtonian region clearly visible at higher shear rate. Although the particle-size distribution is not particularly narrow ($\pm 10\,\%$ of the mean particle diameter), the range of transition times is apparently more dependent on concentration than on particle-size variation. If the dispersion is diluted gradually, the range of relaxation times decreases and the transition region becomes narrower. At any given moment, because of their concentration and lack of free volume, the particles are arranged in random groupings of touching particles, with each group having a different size and, consequently, its own characteristic relaxation time. Thus a range of relaxation times is created. As the system is diluted, Brownian motion and more free volume lead to the breakdown of the largest groups into smaller groups. Thus the range of group sizes becomes smaller, and the range of relaxation times is reduced. In addition, the plateau value of the modulus of elasticity high-frequency decreases sharply. Since this value reflects the total number of particle – particle contacts per unit volume, it supports the particle contact group explanation of the relaxation time range observed [34].

1.3.5. Thixotropic Liquids

In Figure 16, steady shear viscosity measurements are presented for a typical industrial thixotropic material. Here the shear rate is varied continuously through an increasing and a decreasing cycle. Immediately after completion of the first cycle, a second identical cycle of shearing is applied to the sample. Two factors are striking: (1) the first cycle shows a thixotropic loop (i.e., the viscosity – shear rate plot for the descending half of the cycle lies at viscosity values below those for the ascending – increasing shear rate – half of the shear cycle); and (2) in the second cycle, the plots are superimposed on each other. In other words, the sample has now become pseudoplastic in its continuous shear rheology.

Figure 16. Two shear rate cycles (thixotropic material) – – – – = first cycle; —·— = second cycle

These data show two of the characteristics of thixotropic materials. First, an interaction exists between experimental time and material response time. Although not shown here for reason of clarity, increasing the cycle time from the 5 min used here decreases the loop width or area enclosed by the ascending and descending plots, whereas decreasing the cycle time increases the loop width. Furthermore, the existence of a previous shear history, as exemplified by the first cycle of shearing, leads to a change in the sample rheology observed.

Second, although an upper Newtonian limit is approached at the high shear rate of the cycle, no corresponding limiting value of the viscosity appears to exist at low shear rates. Instead, if shear stress is plotted versus shear rate and the plot is extrapolated to zero shear rate, it does not go through the origin but through a positive value of the shear stress, the so-called yield stress (see Section 1.2.2). Although experimental problems occur in obtaining reliable yield stress values, and the physical reality of the yield stress has been debated [21], no doubt exists about the practical reality of such an effect. This is evident in the difficulty of producing flow for these materials, particularly in start-up of operations such as pumping or mixing efficiency in large vessels with paddle stirrers. Such practical difficulties are magnified if elasticity is present in the material at rest.

Figure 17. Oscillatory data for thixotropic material
a) Dynamic modulus of elasticity G'; b) Loss modulus G''; c) Delta; d) Dynamic viscosity η'

The elasticity effects in thixotropic materials can be demonstrated by dynamic (oscillatory) measurements. Data for the same industrial material are shown in Figure 17. Plots of the modulus of elasticity G' and the loss modulus G'' on double logarithmic axes are parallel straight lines (i.e., both moduli exhibit a power law dependence on frequency). This sort of dependence is characteristic of a wide range of relaxation times, with the maximum possible time being infinite. Such a range of times arises from the tenuous structure in terms of both size and degree of branching, and extent of distribution across the volume of the sample. Such structures are characteristic of associating (flocculating) particles in dispersion, associating polymer chains in solution, or mixtures of the two. Since such associations frequently result from physical rather than chemical bond-

ing, they are susceptible to breakage by temperature increase or small mechanical deformation, thus giving rise to other characteristic features of thixotropic materials. These physically bonded structures may extend throughout the sample, giving rise to modulus of elasticity values greater than the loss modulus. However, because of their tenuous network and readily labile nature, they rarely exhibit the predominantly Hookean-type elasticity behavior characteristic of chemically cross-linked polymer gels or very regularly and highly (physically) cross-linked gels, such as the gelatin system discussed [35].

2. Rheological Measurements

2.1. Basic Deformation Modes for Measurement

Two basic modes of deformation are described in detail, namely, shear and extensional deformation. Other modes exist (e.g., bulk or compressional deformation) that are not discussed here.

2.1.1. Shear Deformation

Three submodes of shear deformation exist – simple, torsional, and capillary, or Poiseuille deformation. *Simple shear flow* has conceptual, but little practical, value. Simple shear flow is limited to highly viscous or stiff materials, such as printing ink or asphalt, and can be used in very limited shear rate or total shear strain ranges. Most measurements are made with torsional shear or capillary flow equipment.

Capillary flow is applied to low-viscosity fluids, and gravitational force is used to drive the flow. However, if air or gas pressure is used to drive the flow, fluids with a much higher viscosity can be measured at much higher shear rates. In this way, polymer solutions or melts can be measured. The combination of high viscosity and high shear rate leads to high rates of energy dissipation as heat. Because of the continuous flow of fresh sample into the capillary and the low residence time of a particular volume element of the sample in the capillary, the high rate of energy dissipation usually does not lead to problems of sample temperature control and consequent errors in viscosity measurements.

Torsional shear measurements, in contrast, use the same aliquot of sample confined between the elements of the measuring geometry. Because of the small gap between the elements of the measuring geometry necessary to achieve high shear rates and the reduced sample size, the energy dissipation rate becomes a problem in terms of temperature control. The narrow gap also presents some severe mechanical design problems. However, the narrow gap combined with the relatively large radius of the cup and cylinder (*Couette geometry*) gives a shear rate that is virtually constant across the gap. Although the *cone and plate geometry* is more suitable for achieving uniform shear rate across the sample, the high rotational speed and consequently strong centrifugal forces tend to force the sample from the gap, which limits the maximum shear rate obtainable.

Higher shear rate values can be obtained with the *Couette geometry,* due to containment of the sample within the cup. By contrast, capillary flow leads to a gradient of shear rate across the radius of the capillary. Whereas the gradient can be predicted for Newtonian liquids, this is more difficult if the viscosity – shear rate relationship is unknown. However, because many liquids show near-Newtonian behavior at very low and very high shear rates, capillary flow is more widely applicable than merely as a standard reference measurement for viscosity, despite the difficulty in calculating the shear rate gradient.

2.1.2. Extensional Deformation

Although a large number of commercial rheometers are available to perform torsional flow measurements, relatively few exist for measurement of extensional flow. This reflects the much greater practical difficulty of making such measurements, particularly at high rates of extension or with very mobile liquids. In addition, the problem of generating flows approximating steady extension is by no means trivial. For sim-ple liquids, Trouton's rule states that the

extensional viscosity is three times the shear viscosity value. However, the extensional viscosity of several high molar mass dilute polymer solutions is many orders of magnitude higher than the shear viscosity. For example, METZNER and METZNER [36] measured very dilute aqueous solutions of polyacrylamide (100 mg/L) and found shear viscosities of 1.4 mPa · s and extensional viscosities of 9 Pa · s (Trouton ratio 6500 instead of 3). Other systems showed Trouton ratios as high as 30 000 [37]. Measurements using a different technique substantiate these findings [38]. However, a disparity exists between results obtained with different techniques on the same sample [39]. Practically, only steady-state measurements can be performed because of experimental difficulties. However, stress transients are observable before steady-state flow is attained. Some of the disparities between measurement methods may relate to the failure to obtain true steady-state values or the onset of molecular degradation in high stretching rate flows (dilute polymer solutions).

Two main types of flow in extension have been distinguished by WALTERS [40]. These are (1) uniaxial, and (2) biaxial and two-dimensional flow. Most methodical studies use *uniaxial methods.* Some studies of *biaxial and two-dimensional flow* have been made by DENSON and coworkers [41], in which the formation of bubbles by inflation of small areas of plastic sheet has been studied. Even if the flow may be steady (Eulerian sense), each liquid element must be subjected to a rate of deformation that is independent of time: i.e., transients have died away, and the flow is steady in this sense also (Lagrangian sense). In this latter sense, particularly with low-viscosity liquids at high extension rate, achieving steady extensional flow under practical laboratory conditions is difficult.

Extensional flow has many obvious practical applications in industries based on polymers, for example, fiber spinning, extrusion, vacuum forming, and blow molding. Extensional flow can also be applied in studies, e.g., on surface coatings, atomization during paint application, or the properties of coatings applied by roller coating. Other important areas are lubrication, drag reduction, and flow through porous media (of interest to the oil industry).

2.2. Torsional Shear Deformation

2.2.1. Rheometer Types

Two basic types of rheometer are available for rheological measurement in torsional shear deformation: controlled shear strain – shear (strain) rate and controlled stress instruments. Historically, the former type is older, the first one having been described by COUETTE in 1890.

In controlled *shear strain – shear rate instruments*, the lower member of the measuring geometry is rotated through a small angle (shear strain) or rotated at a controlled speed (shear rate). The sample, confined by the system geometry, exerts a force on the fixed upper member as a result of movement of the lower. This force or torque is measured by means of a sensitive transducer (e.g., a piezoelectric device) or by the (relatively) small deflection of a calibrated torque bar, which couples the upper member to the body of the instrument. The angular deflection or rotation speed is then converted into the applied shear strain or shear rate, and the measured force or torque into the required stress. The applied shear strain or shear rate can be varied in time to increase or decrease linearly, or it can be applied discontinuously with varying rest times between applications.

Controlled stress instruments operate according to a different principle. The lower member of the measuring geometry is rigidly attached to the body of the instrument. By means of a controlled electric current applied to an induction motor, a rotary torque is applied to the measuring head to which the upper member of the geometry is rigidly attached. Movement of the head can be measured by, for example, an optical diffraction grating system, in terms of both angular deflection (shear strain) and angular rotation speed (shear rate). By varying the current, the stress can be controlled as required.

The following applies to both types of instrument:

1) Because of increasing requirements of sensitivity, accuracy, etc., the measuring heads are nearly always supported by air bearings that minimize errors due to friction in bearings.
2) Most modern rheometers incorporate computers that, besides converting measured

(raw) data into the required rheological parameters, also control the experimental procedure. This allows considerable flexibility of control and permits a sequence of inputs to be designed to simulate complex practical situations.

3) When measuring transient properties, a potentially important factor is the input time of the two types of instrument. Thus the imposition of a steady torque by electrical means is extremely rapid. Instantaneous (Hookean) elasticity can be measured since measurement can start 1 ms after commencement of stress application with a measurement rate of $120\,s^{-1}$ in a typical commercial instrument. By contrast, a purely mechanical drive system requires a longer time (rise time) to reach a preset strain level (typically 20 ms to reach the preset strain zero). This results in modification of the short-time stress relaxation behavior observed, particularly if fast relaxation processes occur in the sample. With torque bar measurements, rapid application of the strain leads to an initial oscillating stress (the torque bar behaves like a suddenly struck pendulum). The extent of oscillation and rapidity of decay depend not only on the properties of the measuring head and geometry, but also on the energy dissipative capability of the sample. Although electronic filtration can be used to remove the initial oscillation, it may not be entirely satisfactory. With electrically driven instruments, such instrumental transients are small and of very short duration and do not disturb the measurements.

Some constant-stress instruments are equipped with software that, by using feedback control of stress level, can provide controlled shear rate measurements. Despite the apparent duplication of steady-state, transient, and oscillation measurements on both stress and shear rate instruments, the two types of instrument provide very different and complementary kinds of information. The selection of instrument must depend on both the type of flow application to be studied and the sample to be measured. For example, when studying the flow-out of a wet paint film after application, a stress-controlled rheometer is more appropriate because the flow of the wet paint is caused and driven by stresses or forces originating from gravitational forces and from surface tension gradients on the film surface [42]. In contrast, when studying stirring or mixing problems, shear rate controlled rheometers are more appropriate because the rotation speed of a stirrer blade or a mixing head will determine the shear rates applied to the sample.

2.2.2. Measurement Geometries

The most common geometries of commercial rheometers are parallel plate, cone and plate, and concentric cylinder. Others are available, or can be made, but they have rather more specialized uses. A detailed description of all geometries, together with theoretical considerations, can be found in [9], [43], [44].

2.2.2.1. Parallel Plates

The parallel plate rheometer is a logical development of the parallel plate simple shear geometry (see Section 1.2.3). Instead of a sliding motion, however, the plates are replaced by disks a fixed distance apart, which can rotate about a central axis. This means that both the strain and the shear rate vary across the radius of the disk, from zero at the center to a maximum at the disk edge. This renders parallel plates unsuitable for viscosity – shear rate measurement (unless the liquid is Newtonian). However, the geometry is highly suitable for dynamic (oscillatory) measurements. Because the linear response region is generally used, the strain amplitude variation across the radius is immaterial. The advantages of parallel plates are:

1) Correction for fluid inertia effects is relatively easy (this is important for combinations of low-viscosity liquids and high-frequency measurement)
2) The gap can be varied freely

Fluid inertia effects can be significant, since they depend on the magnitude of the product αh, where h is the plate separation and α is given by the equation

$$\alpha^2 = -\frac{i\omega\varrho}{\eta^*} \tag{1}$$

where ω is the angular frequency (2π times the frequency in Hertz), ϱ the liquid density, $\eta*$ the complex dynamic shear viscosity, and $i^2 = -1$. Clearly αh can be reduced by decreasing the plate distance h, but this procedure has limitations. First, when working with dispersion systems, a value of h more than 50 times the average disperse particle diameter should be used to avoid errors due to wall effects [45]. Second, the narrower the gap, the greater is the likelihood of error due to edge effects, which result from the sample drying at the edge. Examples showing the magnitude of fluid inertia effects are found in [46].

Errors due to *wall effects* arise from the presence of a concentration gradient in particles in dispersion systems (sometimes referred to as the depletion layer). This occurs because the wall exerts a repulsive force (hydrodynamic, not colloidal in origin) on the particle as it approaches. *Loss of solvent* by evaporation during the test is always a problem, because it leads to the buildup with time of concentrated viscous or solid (skin) layers at the sample – air interface. This buildup leads to enhanced torque readings and hence measurement errors. Evaporation can be slowed by coating the sample surface with a layer of immiscible and impermeable liquid; however, the best solution is to saturate the atmosphere around the sample surface with solvent vapor.

2.2.2.2. Cone and Plate (Fig. 6)

To eliminate variation of shear strain or strain rate across the radius of the parallel plate, one of the disks is replaced with a cone (see Section 1.2.3), thus ensuring that the shear rate remains constant. In addition, a small cone angle is required to achieve this [47]. A small part of the cone center is truncated (see Fig. 6), so that it has no direct contact with the plate. Direct contact would result in the risk of friction and, hence, errors in torque measurement and mechanical wear. The smaller the cone angle (measurement at the rim), the greater is the shear rate for a given rotational speed. Cone angles normally vary between 0.5 and 5°.

In addition to the source of error already mentioned under parallel plates, another is due to *errors in gap setting.* To achieve a uniform shear rate, the gap between the cone and the plate must be adjusted carefully so that the cone tip (afterwards removed by truncation) just touches the center of the plate. Since the gap settings are typically between 15 and 60 µm and many commercial rheometers are equipped with a micrometer, dial gauge, etc., that cannot be set to better than 1 µm, errors can be of the order of 2 – 6 %. If programmed temperature tests are carried out on the same samples, errors due to gap setting variation from thermal expansion can be considerable. *Wall effects* can cause serious errors, particularly with concentrated dispersions [48]. *Fluid inertia effects* are particularly difficult to correct, because the α term now appears in the solution of a partial differential equation instead of the ordinary differential equation required for describing responses in parallel plate or concentric cyclinder geometry. A series solution for this equation have been given with Bessel functions and associated Legendre functions in the product αr, where α is as defined above and r is the cone radius [49]. These equations are so complicated that apparently no one has utilized them, even with the aid of computers.

The cone and plate geometry is the obvious choice for viscosity – shear rate measurements. It is not suitable for oscillatory measurements unless fluid inertia corrections can be neglected.

2.2.2.3. Concentric Cylinder (Cup and Bob, Couette)

The concentric cylinder geometry possesses two main advantages over the cone and plate and the parallel plate geometries: (1) a larger shearing surface, and therefore, greater sensitivity when measuring low-viscosity materials; (2) minimization of errors due to drying or skinning at the sample surface – air interface. This last point is not immediately obvious. In normal sample filling, the sample level should be above the top of the bob but below that of the cup. This ensures that most of the torque produced by the sample originates in its bulk as the sample is sheared in the narrow gap between the outer wall of the bob and the inner wall of the cup. Since the shaft of the bob normally has a much smaller diameter than the bob itself, the torque contribution from any thickening with time on the sample surface is minimal. Evaporation from the sample surface tends to be into a stagnant air layer

if the surface level is below the top of the cup, and under such conditions a layer of immiscible, impermeable liquid can easily be placed on the sample surface to prevent evaporation loss. By arranging the system so that the cup and bob radii are large, and the gap between the bob and cup inner wall is small, the shear situation for any small volume element of the sample becomes approximately that of simple shear with uniform shear rate across the gap. In addition, the generally larger sample volumes reduce errors due to heating at high shear rates, and confinement of the sample at high shear rates helps prevent sample loss by centrifugal force effects.

However, the concentric geometry has a major drawback: the corrections required because of end effects (i.e., the fact that some of the torque contribution from the sample is due to the end of the bob, where the shear regime is ill-defined). For example, errors as high as 25 % were found with Newtonian standard oils, using a conventional narrow gap cone ended bob [50]. Other options commercially available are bobs with hollow ends – the idea being to trap an air bubble under the bob. Thus the air pocket reduces the torque contribution from the bob end. However, due to problems from the wetting effects, of shear on the bubble and the rim on the end of the bob, the end effect may still be finite but also variable. Other means of minimizing or eliminating end effects are discussed in [51].

Alternatively, end effects may be *calibrated* out by measuring the torque – angular rotation speed ratio for various heights of sample in the cup. By extrapolating the torque to zero, the extra bob height equivalent to the end effect can be determined and allowed for in viscosity calculations. Within experimental error, these end effect corrections are independent of rotation speed. Corrections must be done for each sample; the calibration for a Newtonian liquid cannot be used [51].

Although end effects appear not to be significant for linear viscoelastic materials in dynamic measurements [52], the effects of *fluid inertia* may be significant. Again, the mathematical treatment of these effects, although easier than in cone and plate geometry, is still more difficult than with parallel plate geometry. A method of approximation using a series to obtain the modulus value is given in [53] and the whole topic is discussed in [54].

2.2.2.4. Other Geometries

Other geometries include double cone systems (one cone fitting into another wider-angle cone containing the sample), various squeezing or sliding flow instruments, instruments with noncoaxial or spherical geometries, and various penetrometers. These are all described in [2], [3], [9].

Whereas most of these have limited general applicability, some are commercially available. For example, the *double cone system* is claimed to be useful for elastic samples, which may fracture when sheared in conventional geometries. *Squeezing and sliding flow instruments* are of interest for very viscous materials (e.g., printing inks), while many types of *penetrometer* (instruments, in which depth – time profiles are measured for a suddenly released loaded needle or other probe) are used in industry for measuring solid and semisolid materials, such as lubricating greases, soaps, gels, foods, or paints.

The *noncoaxial geometries* were potentially of great interest in that they allowed dynamic data to be derived from continuous rather than oscillatory motion. However, they do not provide any significant advantage over conventional rheometers in terms of either the accessible frequency range or the amelioration of sources of error [55].

2.3. Capillary (Poiseuille) Shear Flow

Two main type of materials are tested by capillary rheometers: low-viscosity liquids, where the driving pressure is provided by gravitational force (hydrostatic head type), and high-viscosity liquids such as polymer melts, where the driving pressure is provided by gas or hydraulic pressure. All capillary rheometers are easily temperature controlled. Often when using metal capillaries, good control at elevated temperature is easier than in torsional rheometers. Glass U-tube-type viscometers used for capillary measurements on low-viscosity liquids can be immersed in a temperature-controlled water bath for good control of temperature. Besides being more easily thermostated, capillary viscometers

are generally simpler, cheaper, and more accurate than torsional viscometers.

During the flow of a liquid through a capillary, three regions of flow can be distinguished: entry flow, viscometric flow, and exit flow. The *entry flow region* represents the "funneling" effect of the liquid as it flows from a relatively wide-diameter reservoir into the capillary, and this effect takes some time to relax to its limiting value. Estimates of the length of the entry region vary, it is generally accepted as about 40 times the capillary diameter. To achieve consistent results, the reservoir diameter should be at least 15 times the capillary diameter [56]. In the *viscometric region*, the stresses produced by flow along the tube axis are constant. Clearly, pressure measurements should be made in this region. The *exit region* is induced by the exit of the free liquid stream from the capillary end. It is usually shorter than the entry region. The free stream may have a larger diameter than that of the capillary (die swell) and is often associated with elasticity in the liquid. Experimentally, the length of the viscometric region is maximized by using a sufficiently long capillary tube for the experiment.

The *experimental procedure* consists of measuring the volume flow rate of the liquid and the total pressure drop between the ends of the capillary tube. If the sample is an unknown material, a number of capillaries of different length and interior diameter may be required to establish the flow curve of the liquid and to make suitable correction for end effects (both entry and exit) and other sources of error.

The greatest problem with *interpreting the results* of capillary flow measurements is calculation of the velocity profile across the diameter of the tube. For a Newtonian fluid, the profile can be predicted to be parabolic; for non-Newtonian fluids the profiles can be calculated only if the viscosity – shear rate relationship is known. This can be done for simple rheological models, such as power law or Bingham fluids (→Fluid Mechanics, Chap. 4.1.1., →Fluid Mechanics, Chap. 4.1.2.). However, other models give intractable or complicated mathematical formulas. Although capillary measurement methods are commonly used for non-Newtonian liquids, the results are often presented as flow curves (i.e., pressure drop – flow volume rate plots). Methods do exist for deriving viscosity – shear rate values from flow curve data, but these are valid, in general, only for fluids in which the departure from Newtonian behavior is small. Nevertheless, despite these problems, capillary flow measurements are attractive not only because of their simplicity and cheapness in combination with accuracy, but also because of their ease of application to very high shear rate measurements. With respect to errors and repeatability, the results of capillary measurements on Newtonian liquids are an order of magnitude better than corresponding results on the best commercial torsional instruments [50]. Furthermore, most torsional rheometers are not capable of measuring at shear rates much above $1000\,s^{-1}$ because of the various errors involved. Although the precise limit depends on the geometry and the sample involved, the essential problem is the low sample volume with small gaps and high rate of energy dissipation at high shear rates, with consequent temperature control problems.

In the case of *hydrostatic-type viscometers* such as the Ostwald U-tube viscometer, the driving pressure is set by filling a reservoir with sample and timing, between two graduation lines, the emptying of the reservoir through the capillary tube. Such capillary instruments, usually made of glass, are low-stress instruments (1 – 15 Pa) and have maximum shear rate values of ca. $1 - 20\,000\,s^{-1}$ based on efflux times of 200 – 800 s [57]. Their main use is as secondary standards for viscosity measurements [58], [59], but they are important in establishing the molar mass of polymers or polymer fractions (from gel permeation chromatography separations, for example) by measuring the low shear rate (Newtonian) viscosity of dilute solutions (→Plastics, Analysis, Chap. 5.2.). Another important industrial application is the calculation of liquid flow in pipes.

Finally, *efflux* or *flow cups* are widely used in industry. Basically, these are hydrostatic head instruments, consisting of cylinders with a conical bottom, pierced at the center by a short capillary whose length does not usually exceed the cup wall thickness. They may be operated at elevated (e.g., the Saybolt and Redwood cups used in the petroleum industry) or ambient (e.g., the Ford or BS cups used in the paint industry) temperature. The cup is filled to a mark with the capillary plugged. The plug is then removed, and the time required to fill a graduated flask placed

underneath to a specified volume, or until the fluid stream first breaks into drops is measured. Although these methods give reasonable results for quality control or diluting to a given viscosity (e.g., for spray application of paint), they are not very sound in concept. First, they are totally unsuitable for non-Newtonian liquids because the gravitational driving stress varies considerably due to the large drop in liquid level (ca. 0.06 m) and also the capillary length is so short that viscometric flow is never established.

2.4. Extensional Flow

Extensional flow instruments can be classified according to Nazem and Hill [60]. Controllable experiments refer to those in which the stress or extensional strain rate is kept constant and the steady value of the other parameters is measured. In practice, controllable experiments are applicable only to high-viscosity materials, such as polymer melts. Noncontrollable techniques must be applied to low-viscosity liquids.

Polymers. Polymer specimens are commonly *stretched between two blocks*, one fixed and one movable. This places a constraint on the maximum strain, and hence strain rate, that can be attained because of the finite length of the equipment and the requirement allowing transient stresses to die away to steady levels. By suitable electronic or mechanical means, a programmed force or length increase can be applied so as to maintain constant stress [61] or constant extensional strain rate [62–64]. An improved strain rate controlled instrument has been described that has two sets of rollers at either end of the specimen [65]. This allows a maximum rate of ca. 1 s^{-1}, which is nearly an order of magnitude higher than the other instruments available. Examples of these instruments are commercialy available.

In *biaxial extension,* sheets of polymeric material can be tested either by bubble inflation or by the apparatus developed by Meissner [66] in which an octagonal clamping system is driven by a complex servomotor system.

Mobile Liquids. For mobile liquids, steady-state measurements in both the Eulerian and the Lagrangian senses (Section 2.1.2) are impossible with the present state of knowledge [67]. Therefore, noncontrollable methods are applied. Of these, the laboratory equivalent of fiber spinning equipment is commercially available and widely used [68–73]. The liquid being tested is extruded through a die and collected on a turning spool. Both the diameter of the threadline as a function of position and the flow rate are measured, and the extensional stress is calculated from the force on either the die or the turning spool. The limitation of this method is probably the cohesive energy of the liquid and whether, in practice, a coherent stable thread can be drawn from the liquid.

Alternative methods applicable to more mobile liquids are the open siphon method [74–77], the converging flow method [36], [78–84], the triple jet method [38], and the more recent (commercially available) opposing jets method. In the *open siphon* or *Fano flow method*, the sample is sucked into a siphon until a stable column is formed [75]. This has an advantage over methods involving dies, because the liquid has not suffered any (perhaps unknown) deformation before being stretched [73]. *Converging flow techniques* are simple to use in that liquid flows from a reservoir through an orifice into a capillary. However, analysis of the measurements is difficult, and measurement requires that the liquid be transparent. In the *triple jet technique*, two high-velocity jets converge on a central lower-velocity jet of the same liquid, thus causing the central jet to be stretched. Finally, in the *opposing jets technique,* two jets are mounted horizontally: one on a fixed vertical arm and one on a pivot equipped with a transducer. The jets are immersed in the liquid under test, and liquid is sucked in or blown out through the jets at a controlled flow rate by two syringes also filled with test liquid. The flow rate is controlled by a constant-speed stepping motor, which drives a moving block that pulls or pushes the plungers of the two syringes equally. By measuring the deflection of the pivoted jet and applying a measured but variable force to maintain its position, the extensional stress is obtained. Despite the limitation imposed by the maximum travel distance of the plungers in the syringes, extensional viscosities can be measured at strain rates up to 50 000 s^{-1} or more.

2.5. Measurement Procedures

Three basic measurement procedures are described – steady state, dynamic (oscillatory), and transient – together with a statement of the equation for calculating stress, strain, or strain rate for each of the main measurement geometrics (see Table 1 and Table 2). Because both extensional deformation and capillary shear deformation are carried out only under steady-state conditions, the bulk of this section is devoted to torsional measurements. Extensional flow equations tend to depend on the apparatus and technique used. Detailed discussion of the equations along with their theoretical derivation, is given in [2] and [7].

2.5.1. Steady-State Measurements

Steady-state conditions are achieved by choosing a value of stress or shear rate to apply to the sample and waiting sufficiently long for the measured shear rate or stress value to become constant before proceeding to the next value. Generally, one starts with low applied values and proceeds stepwise to the maximum required value. The sequence is then reversed to check that shearing has not brought about any irreverisble change in the sample. This is necessary for torsional shear when the same sample volume is used for all measurements. When fresh sample is supplied continuously to the measuring region (e.g., in capillary flow), it is not necessary unless the bulk sample is suspected of changing with time, due to sedimentation of the dense dispersion phase, slow phase separation, etc.

In practice, the more solid-like the material, or the more viscous the liquid, or the closer the material is to phase separation or changes, then the longer are the times required to attain steady state. For example, some structured emulsion paints may require 5 min or more to reach a measured value constant to within 10 % over 30 s at a moderate applied stress (100 Pa) [85]. In these cases, thixotropic behavior may have to be accepted for reasons of expediency, i.e., the time required to complete the entire measurement procedure or irreversible changes in the sample over time (e.g., evaporation losses, sedimentation), and the accuracy requirements made less stringent.

The more fluid the material, the more likely is the occurrence of pseudoplastic or Newtonian behavior. In this case, the time to complete the entire measurement may be considerably reduced by using a continuous sweep up and down instead of the stepwise procedure.

2.5.2. Dynamic (Oscillatory) Measurements

Whereas the objective with steady shear measurement is to measure the viscosity over a range of imposed stresses or shear rates, the objective of dynamic measurements is to study the sample as near rest as possible. Shear moduli values are therefore usually measured as a function of applied shear stress or strain at a fixed frequency to define the linear response region (i.e., the range of amplitude values in which the moduli are constant). In practice, the linearity-limiting amplitude does not vary very much with frequency. However, some structured materials have a linear response region at very low applied stress or strain amplitude values, so compromises must sometimes be made between the demands of linearity and the ability of the rheometer to make accurate measurements at low amplitudes.

Few workers have studied the *nonlinear dynamic viscoelastic* properties of materials. Not only are the measurements more complicated and the data more difficult to analyze, theoretical development is still rudimentary, at least in its application to rheological properties. In this respect the work of Onogi and his group should be mentioned [86].

The formulas in Table 2 are applicable to controlled-strain amplitude rheometers only. Those for controlled-stress instruments are similar, but differ in detail.

The equations show the relationship between the measured parameters and the complex dynamic shear viscosity $\eta*$. The measured parameters are the phase angle δ and the stress amplitude θ_0. The ratio of the stress amplitude θ_0 to the strain amplitude input θ_1 is denoted by θ [87].

In Table 2, K and I are the torque constant and the moment of inertia about the axis of the torque-measuring element of the rheometer, respectively; $\omega = 2\pi f$ is the angular frequency (radians per second); and f denotes the measuring frequency (hertz). In the fluid inertia correction

Table 1. Equations for flow shear stress, and shear rate for different measuring geometries

Measuring geometry	Shear stress		Shear rate	
Parallel plate (plate radius R; separation h; distance from center of plate r; angular velocity Ω)	total torque G $G=\int_0^R 2\pi r^2 \sigma \mathrm{d}r$	(2)	$\dot{\gamma} = \frac{\Omega r}{h}$	(3)
	for Newtonian liquid $\eta=\frac{2hG}{\pi\Omega R^4}$	(4)		
Cone and plate [symbols as for parallel plate: θ is angle between cone and plate surface (radian)]	$\sigma=\frac{G}{2\pi R^3}$	(5)	$\dot{\gamma} = \Omega/\theta$	(6)
Concentric cylinder (cup radius R; bob radius r; bob height h)	$\sigma=\frac{G}{2\pi R^2 h}$ where $R = R$ or $r*$	(7)	$\dot{\gamma} = \frac{r\Omega}{R-r}$	(8)
Capillary flow (tube radius a; length l; pressure difference between ends P; volume flow per second V)	$\sigma_\mathrm{w} = \frac{aP}{2l}$	(9)	$\dot{\gamma}_\mathrm{w}=\frac{4V}{\pi a^3}$	(10)
subscript w indicates stress at tube wall	Newtonian liquids only in general, $V=-\frac{\pi a^3}{\sigma^3}\int_0^{\sigma_\mathrm{w}} \sigma^2 f(\sigma)\,\mathrm{d}\sigma$ and $\eta=\frac{\sigma_\mathrm{w}}{\dot{\gamma}_\mathrm{w}}$			(11)

∗ If $r/R = 0.98$, the two stress values agree within 4 % [85].

Table 2. Equations for oscillatory flow∗

Measuring geometry	Without fluid inertia corrections		With fluid inertia corrections	
Parallel plate	$\frac{e^{i\delta}}{\theta}= 1-\frac{i}{\eta^*}S$ with $S=\frac{2h\left(K-I\omega^2\right)}{\pi a^4\omega}$	(12)	$\frac{e^{i\delta}}{\theta}= \cos\alpha h+S'\alpha h\sin\alpha h$ with $S' = \frac{2\left(K-I\omega^2\right)}{\pi\varrho a^4 h\omega^2}$	(13)
Concentric cylinder	as parallel plate, with $S=\frac{\left(R^2-r^2\right)\left(K-I\omega^2\right)}{4\pi L R^2 r^2\omega}$	(14)	$\frac{e^{i\delta}}{\theta}=\frac{\pi r^2}{2R}X$ $\{\alpha[J_2(\alpha r)Y_1(\alpha R)-Y_2(\alpha r)J_1(\alpha R)]+\alpha^2 S''X$ $[J_1(\alpha r)Y_1(\alpha R)-Y_1(\alpha r)J_1(\alpha R)]$ with $S''=\frac{K-I\omega^2}{2\pi\varrho r^3 L\omega}$	(15)
Cone and plate	as parallel plate, with $S=\frac{3\alpha\left(K-I\omega^2\right)}{2\pi r^3\omega}$	(16)	see [49]	

∗ For explanation of symbols, see Section 2.5.2.

term $\alpha^2 = i\omega\varrho/\eta*$, where ϱ denotes the density of the sample and $i^2 = -1$. For parallel plates, h denotes plate separation and a the plate radius; for concentric cylinders, R_0 and R_I denote the radii of the outside (internal cup radius) and the inside cylinders (bob), respectively; L is the bob length; and J and Y are Bessel functions of the first and second kind. Finally, for the cone and plate geometry, α_0 and r denote, respectively, the angle between the cone and the plate and cone radius.

Resolving Equation (12)

$$\frac{e^{i\delta}}{\theta} = 1 - \frac{i}{\eta^*}S \tag{12}$$

for the elasticity modulus components yields

$$G' = \frac{\omega S\theta\,(\cos\delta - \theta)}{\theta^2 - 2\theta\cos\delta + 1} \tag{17a}$$

$$G'' = \frac{-\omega S\theta\sin\delta}{\theta^2 - 2\theta\cos\delta + 1} \tag{17b}$$

The corresponding equations for the controlled stress rheometer are

$$G' = C\,(\theta\cos\delta - 1) + \frac{CI\omega^2}{K} \tag{18a}$$

$$G'' = C\theta\sin\delta \tag{18b}$$

$$C = \frac{\pi a^4}{2hK}$$

The equation taking account of fluid inertia effects is also simpler for controlled-stress instruments [85]

$$\frac{e^{i\delta}}{\theta} = \frac{K - I\omega^2}{K} + iC\alpha h\eta^*\omega\cot(\alpha h) \tag{19}$$

Besides fluid inertia effects, other sources of error can occur in dynamic measurements due to natural frequency effects and sample stiffness. The sample stiffness is, however, rarely important. Correction methods have been described [88], but the situation should be avoided by ensuring that θ is always small compared to unity.

The *natural frequency* ω_0 of the measuring system is given by $\omega_0^2 = K/I$. At this frequency, $\theta = 1$ and $\delta = 0°$ for controlled-strain experiments and the values of G' and G'' become indeterminate (Eqs. 17, 18). However, for controlled-stress instruments, $\delta = 90°$ and, again, the G' and G'' values are indeterminate. Although accurate values can be measured on either side of the natural frequency, at higher frequencies the accuracy of measurement becomes more limited as frequency increases beyond the natural frequency value. This is due to the increasing dominance of the inertia term ($I\omega^2$) on the right-hand side of Equations (17) and (18) [89]. A better procedure is to shift the value of the natural frequency by changing either K (by using, for example, a stiffer torque bar) or I (by altering the mass of the measuring geometry – e.g., substituting a glass or plastic cone for a steel cone or using a smaller-diameter cone). By this means, the natural frequency can be shifted out of the required frequency range.

In addition to the forced oscillation (i.e., where an oscillation frequency is imposed on the sample – measuring system combination), the system may be in so-called *free oscillation.* However, this technique should properly be classified as a transient method (see Section 2.5.3).

2.5.3. Transient Methods

In the free oscillation method, the sample – measuring system is deflected (usually in torsion), then released and allowed to oscillate until damping by the sample stops the oscillation (→Plastics, Properties and Testing). The oscillation frequency and the amplitude decrease (decrement) per cycle are measured. Because the oscillation frequency can often be arranged by judicious choice of mass, etc., to be in the 0.1 – 2-Hz range, measurements can be made rapidly. Its speed of measurement and inherent simplicity make this an attractive technique for studying rapid changes in rheological properties during, for example, resin curing or polymer cross-linking. Using a woven braid to support the initially low-viscosity fluid, GILLAM and coworkers have made extensive use of this technique [90]. The other primary transient methods are creep and stress relaxation (→Plastics, Properties and Testing). In *creep measurement,* the sample undergoes a stepwise increase in stress, and the resulting strain is measured as a function of time. The stress is then removed, and the decay of strain with time is followed. In the *stress relaxation experiment,* a stepwise strain is applied to the sample, and the resulting stress is measured as a function of time until the stress either decays to zero or becomes constant.

When using, for example, parallel plates in a torsional shear stress relaxation test, the modulus of elasticity $G(t)$, defined as the stress $\sigma(t)$ at time t divided by the applied strain γ, is given by

$$G(t) = \frac{2hT}{\pi R^4\varphi} \tag{20}$$

where T is the measured torque at time t and φ is the angular deflection (radians). In general, the equations in Table 1 may be used to calculate stress, and by substituting γ for $\dot{\gamma}$ and φ for Ω the strains can be found. In creep measurements the compliance $J(t)$ is often calculated.

The same considerations still apply in choosing measuring geometries, and cone and plate geometry is probably best wherever possible. In addition, the rise time (i.e., the time to reach the chosen stress or strain value from an initial zero value) must be taken into account. Ideally, the sample's relaxation times should be longer than the rise time. The application of sudden deflections to a torque bar can lead to initial free oscillations that can swamp sample response in the initial few seconds of a stress relaxation experiment. The magnitude of these oscillations depends on the brevity of the rise time, the strain value applied, and the stiffness of the sample. This last factor can be reduced by increasing the gap between parallel plates, reducing the cone diameter, etc.

2.5.4. Combined Methods

With the aid of computer software, many commercial torsional shear rheometers can provide any required combination or sequence of basic measurement procedures just described. This is particularly useful in two ways. First, many structured materials are very sensitive to stress or strain and have very long *recovery times.* Consequently, the procedure of sampling from the bulk and loading the sample in the rheometer may impose sufficient stress or strain to change its properties significantly (i.e., the sample may suffer unknown deformations before measurement). The long recovery times may mean that even leaving the sample for a long time before measurement is not sufficient for it to return to its original state. This can be circumvented by imposing an initial deformation history, for example, by applying a shear rate until a constant stress value is obtained. The measurement can then be carried out immediately afterwards, and the effect of varying the initial history on the measurements can be studied. The second possibility is that by varying the time interval between the completion of the initial history and the start of measurement, the recovery process can be determined. Particularly useful in measuring recovery processes are repeated oscillatory measurements over a period of time at single frequencies or (better still) superimposed multifrequency waveforms, which are becoming available in many software packages. Such techniques are also useful if the sample is changing with time because of some other effects than relaxation, e.g., chemical cross-linking.

The second way in which such combined methods are useful is to *simulate complex flow problems.* For example, paint applied to a vertical wall is spread by the high stress exerted by a roller or brush; the wet liquid film should then remain unchanged under the influence of low stresses due to gravity. This unchanged state should remain for up to 5 min, after which viscosity increases or the appearance of elasticity – due to the loss of solvent by evaporation (drying) or the onset of curing – prevents further change. If flow does occur under the influence of gravity, it sometimes does not show immediately, but appears after a few tens of seconds as drips, runs from edges, and wavy irregular patterns of uneven thickness. These, of course, spoil the appearance and protective power of the final paint coating. This process may be simulated by applying a high stress for a short time (brush application), followed by a creep measurement made at small applied stress (0.2 – 5 Pa), which can be varied to simulate variations in wet-film thickness and specific gravity. The creep measurement will then show whether significant flow occurs at a specific stress (film thickness) and within a certain specified time (drying time).

Other examples stem from the tendency of many disperse systems to form *structures or become solid-like* when at rest for long periods. Whereas such structure usually breaks down when a stress or strain is applied to it and the material liquefies, in the design and operation of pumping and mixing equipment, the pressure (stress) or mixing speed (shear rate) required to liquefy the sample and the length of time for which it should be applied, must be known. Rheological measurement procedures can be designed to simulate these conditions, whereas dynamic measurements can be used to probe the nature and strength of the structure at rest.

2.5.5. Normal Stress Measurements

When an elastic liquid is sheared (e.g., a polymer solution or melt) a significant component of the total force is often developed in the liquid, which is in a direction normal to the direction of

shear. Thus, in addition to the shear force usually measured, a significant force may be measured by mounting a suitable transducer in the face of the cone or plate of the measurement geometry. These so-called normal forces lead to rod climbing or Weissenberg effects (→Fluid Mechanics, Chap. 4.3.) in which such liquids form a convex meniscus around a rotating stirrer rod or shaft [91], [92].

Normal force effects occur in all the basic measurement techniques, provided the material possesses sufficient elasticity and is fluid enough to be sheared without sample fracture. Dispersion systems, particularly well-stabilized ones, do not usually possess sufficient elasticity, even when very concentrated, to exhibit measurable normal force values. Methods for measuring normal force in continuous shear have been described in [93]. In dynamic measurements the measured normal force oscillates at twice the applied frequency [94].

3. Results of Rheological Measurements

Reviews of rheological results and theory include [10], [12], [14].

3.1. Steady-State Measurements

At low concentrations, both polymer solutions and dispersions follow Einstein's formula and are Newtonian liquids (viscosity independent of shear rate)

$$\eta_r = \frac{\eta_o}{\eta_s} = 1 + 2.5\varphi \tag{21}$$

where η_o is the viscosity at low shear rate, η_s is the solvent or dispersion medium viscosity, and φ is the total phase volume occupied by the polymer molecules or particles.

The number of interactions increases with increasing particle or molecular concentration, either by interaction through collision or by modification of the flow fields around the particles and the mutual interaction of these fields. These interactions increase the amount of energy dissipation per unit time during shearing, and consequently, the overall viscosity of the dispersion or solution also increases. Finally, at ca. 20 % volume concentration, the number of interactions becomes sufficiently large that the effect of strong shearing is to reduce their number and intensity by changing a random, three-dimensional fluctuating network of interactions into a less random, two-dimensional fluctuating network. Such reduction in interactions results in less energy dissipation and, consequently, a lower viscosity for the whole system. This leads to the appearance of two Newtonian viscosities: a high value corresponding to the three-dimensional random situation at low shear rate (lower Newtonian plateau) and a lower value corresponding to the more ordered situation at high shear rate (upper Newtonian plateau). At intermediate shear rates, the viscosity is shear rate dependent. At these intermediate values, a balance is struck between the shear rate trying to order the system and the thermal motion of the solvent molecules trying to disorder the particles or solute molecules. This balance may be achieved rapidly. If the interactions are relatively strong, the rate at which the balance is reached may be of the same order or greater than the rate of change of shear rate (if the shear rate is constant for a certain experimental time, then the time to reach balance may exceed the experimental time). This has two consequences:

1) The flow behavior shows time dependence (i.e., it is thixotropic rather than pseudoplastic)
2) Because the associative interactions lead to a higher effective concentration or a higher phase volume than that of the actual concentration, the onset of shear rate dependence of the viscosity is observed at much lower concentration than 20 % phase volume

Shear rate dependences are shown diagrammatically for dispersions in Figure 12 and for polymer solutions in Figure 18. Well-stabilized dispersions usually show a stronger dependence on shear rate of viscosity than polymer solutions, as indicated.

As the concentration increases, the increasing number of multiple interactions leads to greater increases of viscosity for each equal increment of concentration. Both the upper and the lower Newtonian values increases sharply, but the difference between them also increases (i.e., the shear rate dependence becomes stronger). Finally, a critical volume fraction is reached at

which the particles of the dispersion or the solute molecules have so little free volume that they are in contact with each other constantly, thus forming a network throughout the volume of the liquid. At this point, the viscosity of the liquid becomes infinite and the liquid exhibits solid-like behavior. Finally, if the volume fraction becomes higher, even these rearrangements under continuous shearing will be impossible, and the material becomes entirely solid-like. These changes normally take place over an effective phase volume fraction of 0.50 – 0.72.

Figure 18. Viscosity – shear rate profile for polymer solution (diagrammatic)

Differences occur between different systems in this critical volume fraction range. Thus, well-stabilized *hard particle dispersions* exhibit very abrupt changes in viscosity over a narrow concentration range, whereas the changes in *polymer solutions* are far more gradual, due to changes in the polymer molecular volume as the concentration increases. In dilute polymer solutions in a thermodynamically good solvent, the macromolecular coils are fully expanded. As the polymer concentration increases, polymer – polymer interactions becomes stronger than polymer – solvent forces. As a consequence, less solvent is "trapped" within the polymer coil, and the coil contracts in volume until it reaches so-called unperturbed dimensions [95]. Beyond this minimum volume, coils can still overlap or entangle as concentration increases further. Thus the volume shrinkage leads to an initial small change with concentration (dilute solution), then a more rapid change over a fairly wide concentration region where the swollen coils come closer to each other and contract to the unperturbed dimensions (semidilute solution), and then finally a steep viscosity increase with concentration due to overlap (concentrated solution). This last increase is not usually as strong as in concentrated dispersions, due to coil flexibility, and continuous measurements are possible up to 100 % polymer content. Because hard particles are not flexible, continuous shear measurements on concentrated dispersions are not possible beyond a certain critical maximum volume packing fraction, which seems to depend on the nature of the stabilization often around that corresponding to random packing (0.639) for sterically stabilized [96], and higher (0.74) for charge-stabilized dispersion [97], [98].

Some *bimodal particle dispersions* can be fluid up to volume fractions of 0.85 or slightly more, if the relative particle sizes and the concentration of each size are chosen carefully [99]. Apparently, when the large particles reach the critical packing fraction, the smaller particles can fit in the interstices between them. Emulsions can also reach similar phase volumes before the overall viscosity becomes very high [100], because the droplets can undergo distortion (due to the flexibility of the interface and the fluidity of their interiors) and pack in hexagonal cross-sectional structures. The continuous phase is then confined to the interfacial surfaces and small pockets where more than two interfacial surfaces meet. The maximum phase volume that can be reached usually depends on the onset of phase inversion. Similar considerations apply to foams (gas-in-liquid dispersions), but in practice, because of the much greater overall fragility of the structure compared to emulsions, they are usually unable to sustain much shear.

Polymer melts exhibit a similar transition in viscosity behavior with (average) molar mass. Thus at low molar mass, the macromolecular coils are not long enough to overlap or entangle and are in their unperturbed dimensions. As molar mass increases, the (low shear rate) viscosity becomes dependent linearly on the molar mass. Beyond a certain critical molar mass, overlap or entanglement commences and the viscosity becomes dependent on molar mass to the (average) power of 3.4. A more or less pronounced transition region may occur, due to the effects of molar mass distribution [101].

Additional effects may occur in *charge-stabilized dispersions,* due to the presence of charged ions of opposite sign to those on the particle that are attached to the particle surface, by

either chemical bonds or adsorption of charged stabilizers (surfactants or polymer molecules). Thus a charge double layer is formed at the surface of the particle. The thickness of this layer depends on the electrolyte concentration in the dispersion medium; indeed, if the medium is carefully deionized by dialysis or similar techniques, the double layers can extend so far that even dispersions as dilute as 2 % phase volume can show solid-like characteristics and, if the particle size is uniform, quasi-crystalline ordering [102], [103].

Anisotropic particles often exhibit effective phase volumes different from their geometric volume. Such particles may also show specific effects due to interactions when oriented in velocity gradients, for example (rheopectic flow). *Micellar systems* often exhibit effects intermediate between emulsions and dispersions as concentration increases. *Liquid-crystal systems* share some of these properties, but their extreme anisotropy leads to many interesting and complex rheological phenomena [104]. The rheological properties of emulsions, micellar, and liquid-crystal systems are often extremely temperature sensitive.

Finally, net attractive forces between particles in dispersion or between particles and polymers dissolved in the medium can lead to the formation of complex space-filling structures (*flocculates*), whose effective phase volume may vastly exceed the phase volume of the particles alone. If such structures form a network throughout the volume of the liquid, it behaves like a solid at rest or low shear rates (infinite viscosity). If such structures are separated by a reasonable volume of medium, flow will occur but the viscosity will be much higher than that expected on the basis of the dispersion phase volume alone. However, unless the attractive forces involved are very strong or covalent bonding is involved (e.g., in a polymer gel), these structures will be broken down readily by shearing, and continuous shear rate measurements will indicate pseudoplastic or (more likely) thixotropic flow.

3.2. Dynamic (Oscillatory) Measurements

For a Newtonian liquid, the loss component G'' of the complex dynamic modulus of elasticity $G*$ shows a plot of slope of unity against frequency on double logarithmic axes, whereas the elasticity component G' is much lower [61], often impossible to measure. This is equivalent to a constant real component of the dynamic shear viscosity η' that is independent of frequency (i.e., Newtonian).

Few liquids exhibit viscoelastic responses that are characterized by single relaxation times. Exceptions are some micellar solutions, particularly a number of cationic surfactants, which in the presence of certain organic anions, form long stiff micelles. These solutions possess very definite viscoelasticity, probably due to the formation of transient networks resulting from random interlocking of the very long stiff micellar rods. A typical example is the 0.1 mol/L 1 : 1 molar ratio cetyltrimethyammonium bromide – salicylic acid solution (see Fig. 13, Section 1.3.3). Apart from these systems, neither simple supercooled liquids (supercooled to bring the transition region within the frequency range of the dynamic mechanical equipment; dielectric measurements do not have this restriction, but even at ambient temperature, nonassociating liquids usually exhibit a range of relaxation times [105], [20]) nor dispersion systems exhibit such behavior, although some dispersions may have very weak viscoelasticity of this kind over a limited concentration range [34]. Most simple liquids, micellar solutions, colloidal solutions, emulsions, and dispersions have a wider transition region from predominantly viscous to elastic properties. Thus, crossover ($G' = G''$) occurs at a lower frequency than the G'' peak, with the crossover frequency corresponding to the longest characteristic time of the system. Such a range of characteristic times reflects a restricted range of free volume and interactions available to each disperse phase particle or to each liquid molecule in the case of supercooled liquids (see Section 1.3.4).

The range of characteristic times is limited by comparison with a *polymer macromolecular chain,* where the chain can be modeled as a string of beads connected by springs, with each bead dissipating energy by frictional resistance with the surrounding medium (whether it be a liquid, as in polymer solutions, or other macromolecules, as in polymer melts). For flexible chains or high molar masses, the number of beads can be large, and the range of char-

acteristic times and the transition region correspondingly wide. The theories developed on this general model by BUECHE [106], [107], ZIMM [108], ROUSE [109], SLONIMSKY [110], and others show a particular distribution of characteristic times, and predictions based on these theories agree well with experimental data. A typical data set for a concentrated dispersion is shown in Figure 15, and for a polymer solution in Figure 19.

Figure 19. Oscillatory profile for polymer solution (diagrammatic)
a) Dynamic modulus of elasticity G'; b) Loss modulus G''

If the particles in a dispersion are *flocculated,* the floccules tend to be linear, highly branched, or fractal structures and then the possibility of wide distributions of characteristic times exists, with the maximum times being very large if structures filling the liquid volume are formed. This process becomes analogous to the changes in dynamic mechanical behavior of a gelling polymer system with reaction time (→Polymerization Processes, Chap. 2.1.3.). Thus, initially, the dispersion is viscous or viscoelastic with a wider transition region than Maxwell liquids. As flocculation or gelation proceeds, the transition region widens close to the gelation point. At this point, the region is so wide that both components of the complex modulus (G', G'') show power law dependence on frequency with exponents less than unity. Beyond this point, the strength and number of links in the polymer gel network or particle network increase. Because of this, the exponent of the modulus of elasticity G' – frequency power law relationship decreases toward zero, and G' becomes progressively greater than the loss modulus G'' over the entire frequency range (normal frequency ranges, 0.001 – 40 Hz, supplied by typical commercial rheometers are assumed). The changes and the viscoelastic properties characteristic of each stage of this process are shown in Figure 20.

a) Dynamic modulus of elasticity G'; b) Loss modulus G''

3.3. Transient Measurements

The two major types of measurements used are constant stress (creep) and constant strain (stress relaxation). Other methods – for example, measurements of stress transients on application of a constant shear rate or of stress relaxation on

removal of constant rate of shear – are less frequently employed because of measurement errors and limited applicability. They are used quite often to confirm the predictions of constitutive equations. Of the two main methods, creep often gives more obvious indications of structural change.

Figure 21. Creep (anelastic behavior)
a) Retardation (stress on); b) Relaxation (stress off)

Even allowing for instrumental errors, few *solids* exhibit perfect Hookean behavior, except at low stress or strain or short times. Many solids exhibit elastic behavior, as shown in Figure 21 for a creep experiment. This is typical of many metals (→Mechanical Properties and Testing of Metallic Materials, Chap. 2.7., →Mechanical Properties and Testing of Metallic Materials, Chap. 2.8.), polymers (→Plastics, Properties and Testing), etc. An initial instantaneous deformation is followed by a gradually decreasing deformation, which reaches a constant strain value after sufficient time. When the applied constant stress is removed, an instantaneous reduction in strain value occurs, followed by a slower time-dependent reduction of strain to the initial zero value. No irreversible deformation occurs, and thus no dissipation in the deformation process. Essentially, anelasticity can be defined as Hooke's law behavior extended to include the time dependence of deformation, as first done by Zener [111]. Two additional constraints are added: (1) at any value of time, the deformation (strain) is proportional to stress; and (2) given sufficient time, the strain will always reach an equilibrium value. Thus, although the modulus or compliance is time dependent, it is not strain or stress dependent.

Structured liquids and *weak solids,* such as paints and swollen gels, exhibit true viscoelastic properties. These are shown in Figure 22, again for creep experiments. Compared to elastic behavior, two essential differences can be seen. First, after a sufficiently long time for stress application, the strain becomes a linear function of time (i.e., some true viscous flow occurs, usually at avery low shear rate, and no equilibrium strain value is reached). Second, when the stress is removed, the strain value tends to an asymptote (i.e., a finite nonzero strain value at long times). So no recovery to zero occurs. However, when these plots are converted to compliance – time plots for different stress values, they may still be identical (i.e., the viscoelasticity is linear in nature). Apparently, in such materials, numerous strong-bonded volumes exist, whose boundaries have weakly bonded interfaces. At low stress, the weak bonds of the interface break, allowing some relative and irreversible movement of the volumes. Many of these interfacial bonds can reform in new positions due to the slow relative motion of the volumes. This ensures some recovery from the deformed state when the stress is removed [111], [112]. However, at higher stress, the response is still viscoelastic, but no longer linear. At still higher stress, total breakdown of structure and rapid flow takes place, as shown by the sharp increase in strain value with time and the slight or zero strain recovery when the stress is removed (Fig. 23).

Figure 22. Creep (viscoelastic behavior)
a) Retardation (stress on); b) Relaxation (stress off)

Figure 23. Creep (breakdown to flow)
a) Retardation (stress on); b) Relaxation (stress off)

Similar but less distinct changes can be seen in *stress relaxation plots* as the strain value increases. Thus an initial constant stress value is observed, which then declines either toward zero (flow) or to another constant value (gel). Progressive increase in strain may give modulus – time plots that are identical (linear response), and then the initial stress plateau may decrease or last for a shorter time before disappearing entirely. Finally, a rapid decline to zero stress indicates flow.

1. Introduction

Laboratory information and management systems (LIMS) support both the administrative tasks of order processing and also the acquisition and assessment of results in the laboratory. LIMS "informs" about results and "manages" order processing.

The laboratory as a production center for discoveries – and so subject to the rules of production planning – is a new and unfamiliar idea. The laboratory is still being recognized as a creative (innovative) work center with a problem-oriented working procedure for nonrecurrent problems. Work of this kind is generally considered to be unpredictable and therefore only plannable to a limited degree. If this was true, however laboratory work could not be combined with the systematic arrangement that supports an information system, and data processing support in the laboratory would only be of minor importance.

In an analytical laboratory, orders and work flow can effectively be dealt with according to a plan and guidelines. For every laboratory there is a limited, yet established array of services depending on the instrumental equipment, the qualifications of personnel, and the objects to be analyzed.

Orders, samples, and analytical methods can be systematically described by a suitable data model.

Laboratory orders are plannable and can be carried out according to the rules of operations scheduling. The uncertainties of time for laboratory orders are greater for material and methodical reasons compared with production planning. In the laboratory operations scheduling is usually controlled with less attention to particulars. Nevertheless the preconditions exist for a time, capacity, and personnel plan together with those for an order processing procedure supported by data processing. Laboratory information and management systems undertake these tasks.

2. Definition

2.1. Historical Development

The handling of large data streams such that arise in spectroscopy and chromatography, e.g., autosamplers in chromatography, led to the development of laboratory data systems. Initially these systems took over control functions for instruments, but were later developed into laboratory-wide management systems with the functional areas of data acquisition, evaluation, and order management. LIMS has developed from initially central solutions (host) with a comprehensive problem definition to administrative systems at departmental computer and networking level. Contributing to this development were the decreasing prices for hardware and the promising development of instrumental analysis (on-site information). The availability and use of relational data bank management systems represented a further innovative step in the development of LIMS. It also introduced a transition to the more extensive use of standard software, and solution by an individual program was increasingly supplanted. Most of LIMS development is definitely in the technical field, with little innovation in functionality, i.e., in the rules by which the data are processed. With respect to functionality, in addition to the sample-oriented character that is still preferred today, an extension to order- or project-related applications becomes apparent. At the same time a development fostered by quality assurance can be recognized: the LIMS application is no longer regarded as an isolated solution for the laboratory, but rather is understood to be a component or an element of quality management and assurance for the entire company.

2.2. Outline Solutions

In outline solutions, the goal is to start out from commercial standard software. This is supported by the rapid development of relational data bank management systems. One of the great advantages of such systems lies in a flexible adaptability of the functionality to (future) requirements. However, the use of relational data bank management systems simultaneously makes new and greater demands on the efficiency (speed, security of access) of the hardware.

The data processing implementation of LIMS was pushed further and further into the background in favor of the specific application.

2.3. User Expectations

The user expectations of data processing systems have developed with the available possibilities. The demands for user friendliness and operating convenience have increased. This development is taken into account by graphical user interfaces (GUI) and interactive auxiliary functions, but the user also expects an improved and expanded system functionality. Systems can be adapted and configured to different tasks by the user without programming operations. One of the areas of LIMS development is the integration of software extraneous to LIMS. The specialized software packages are so integrated into the functionality of LIMS that a continuous form of processing is obtained. Globally, the task of LIMS as the exchange of data between LIMS and other data processing applications becomes an absolute necessity.

2.4. Task Areas (see Fig. 1)

Figure 1. Laboratory data processing using LIMS

LIMS mainly covers the administrative part of support in the laboratory. The main objectives are order management and the collection of results together with the resulting archiving functions. Traditionally, LIMS has been a sample- or object-oriented system for an analytical laboratory. LIMS is being expanded to form a support for an order-oriented or (more

comprehensively) a project-oriented operating procedure of research and development laboratories. The *sample-oriented* form can be understood as a subgroup of the project-oriented form. By this definition, the *order-oriented form* is the connecting link between these two types. The *project-oriented form* is based on the processing and examination of samples, but in addition it contains features of a system of project management with respect to time and content and a system of project documentation.

2.5. Functionality

The LIMS functionality is directed to the task of providing a service. No recognized LIMS standard exists, but there is substantial agreement on the functionality of LIMS applications. The user expects and assumes large functional differences in the individual LIMS applications. However, since the laboratory problems are in fact not that different, the real functional differences between systems result essentially from the limitation of central LIMS functions to individual tasks specific to the company. These include, for example, terminologies, reporting, and forms of data evaluation. The central functionality, i.e., the actual laboratory procedure, shows no fundamental differences. In terms of the LIMS data model, this means that the assumed differences lie mostly in the information that describes tasks and samples and not in that necessary for the operational sequence.

3. Objectives

Compared with other investments in the laboratory, the introduction of a LIMS is exceptional by virtue of the costs and the project duration. In addition to the external costs for hardware, software, and services, further requirements are the preparation of the master data and introduction of the system. This investment requires an economic justification. Measurable and quantifiable benefits are *rationalization effects*, performance increases, and task extensions, which occur both in the laboratory and in other areas of the company. Further positive but not immediately quantifiable consequences result from the higher standards of work expected.

In addition to rationalization, the second aspect, an *improvement in quality* of the laboratory work, is equally important together with the creation of *centralized information* on quality data. Aspects such as *quality assurance* and *data exchange* have also become more significant. Without a LIMS, developments as initiated by computer-integrated manufacturing (CIM) or total quality management (TQM) are scarcely conceivable and not practical.

The systematic approach leads to working rules for the laboratory that are indispensable for a quality assurance system. In addition, the laboratory work becomes both internally and externally comprehensible.

Following the systematic approach required by LIMS, a data base also is created that allows meaningful archive evaluation. Of the secondary reasons for introduction of LIMS, the continual availability of information is especially important.

As a result of appropriate data processing support as provided by a LIMS, conditions are created for evaluating data at a complexity appropriate to a specific problem. Manual data processing, which also is possible in principle, is generally not practiced due to the cost of reliable data gathering, the time required for processing, or the lack of technical competence.

4. LIMS in an Information Network

A laboratory data system must not be considered solely from the perspective of the laboratory; the global company environment also must be taken into account. This results in additional demands for extending communication beyond the laboratory.

Data that are valid throughout the company are thus incorporated in the master data base of a LIMS. In principle, therefore, such general data could be accessed by the LIMS (i.e., not filed in the master data base) to avoid a redundant holding of data (and consequently problems with the data files developing in separate directions). However, the utilization of general data files by LIMS instead of using its own master data base is not yet possible, since the continual availability of data for the LIMS cannot yet be guaranteed. In the same way, organizational difficulties

such as systematic arrangement, competence, or responsibility are obstacles to the consistent application of distributed data banks.

Alongside the LIMS computer system in the laboratory, there are usually other computing systems (GC, HPLC, spectroscopic, and workstations). These subsystems are to be subsidiary to the LIMS. At the same time the distributed intelligence at work stations and analytical instruments is used so as to prevent too much interference with analytical processing as a result of malfunctions. Outside the laboratory area, computer applications exist in which laboratory or laboratory-relevant data are processed or managed (e.g., commercial applications, process control systems).

The demarcation of LIMS to systems of the latter kind is relatively easy, because these processing and managing systems do not directly influence current laboratory procedures. In these external systems, data are filled once the processing of an order is complete. Data from these systems are retrieved by LIMS for updating its own data files. This data transfer is merely a technical problem (and a problem of data format conversion). The inclusion of analytical subsystems in LIMS, on the other hand, which lead to different forms of data exchange requires individual, complex solutions. The data flow resulting from this must be fully integrated into the LIMS functionality.

5. Nature of a LIMS

A LIMS is described by its data model and the functionality. Within this framework a LIMS is designed by the user. The description of the analysis and the samples is particularly important since the samples constitute the object of processing, the analysis the form of processing in the laboratory work.

5.1. Data Areas

In principle, three forms of logical data area exist in a LIMS:

1) Master data
2) Dynamic data or order data
3) Archive data

The *master data base* contains the "knowledge" of the laboratory, and thus all information necessary for carrying out the work there. It consists of general, analytical, and task-describing tables. The information contained in the master data base includes among other items the description of the organization, the authorities of personnel, and the descriptions of equipment, analytical methods, and samples. In addition, processing of different orders is described in the master data base. This includes sampling plans, analysis plans, monitoring of testing agents, and processing strategies according to experience. When an order is received, this master data base is always re-accessed and with the information filed there a task is set up in the *dynamic data area*. The raw data are assembled in this temporary data area and, with validation, transferred to the *archive area*. The archive thus originates in the master data.

5.2. Functional Principle

A LIMS is an information system built on experience. Flexibility and adaptability of the system therefore depend on the collection of master data which reflect the user's experience and his "view of the laboratory world". The master data are updated in a dynamic process by new experiences. Due to this continually expanding basic knowledge, LIMS are influenced by experience and is adaptive. If a master data base is of poor quality, therefore, only limited benefit can be expected from the use of even functionally very powerful systems.

5.3. Analysis – Sample

The analytical method is a measuring process that is applied to a sample (object) and whose outcome can comprise one or more results. The sample itself is not characterized by the analytical method, but is described by its own characteristics. The processing of samples (analyses) generates the processing order. The project is made up of various orders (individual steps of a project). The existing logical distinctions between project, order, sample, and analytical method must be reproduced in the data base of the LIMS.

Structure of an Analytical Method. An analytical method is modeled in LIMS in the form of its algorithm (procedure). This procedure must not process nonanalytical information, otherwise the necessary validity is lost.

Test Values – Statistical Characteristics. In addition to the procedural models, method-related statistical evaluations of analytical results must be defined in LIMS. The individual results are characterized by range of application, significance, and precision (e.g., standard deviation, repeatability, reproducibility), which are all filed together with the analytical method.

Calibration. For the calculation of analytical values, prior calibration or access to calibration values for the instruments or methods used is necessary in many cases. These calibration values and the calibration planning are assigned to the method, with consideration taken for the instrumental equipment.

6. Forms of Order

In principle, three forms of order are possible:

1) Frequency-controlled orders
2) Event-controlled orders
3) Random orders

For frequency- and event-controlled (routine) orders, the order data are known within the LIMS, but the *random order* must first be set up on the basis of the master data. It is therefore advisable to provide different functions for recording routine and additional orders.

Production monitoring is usually carried out in a frequency- or event-controlled manner. LIMS uses the corresponding work schedules for several purposes:

1) Sampling schedule
2) Automatic prerecording of orders
3) Order recording
4) Capacity planning
5) Cost accounting

In addition to the routine and medium-term processing of individual samples, all-encompassing mechanisms that enable long-term and project-oriented processing are desirable. These forms of order require individual activities to be planned with regard to time and content. The project orders filed as a network are monitored and controlled by LIMS by means of statements of internal costs and status reports.

From the recorded project schedules, the project activities are described in detail by means of a sample-oriented order-processing schedule. With this, a new sample-oriented order which describes the processing of actual samples, is created for each individual step of the whole project.

In the description of an order the LIMS treats separation operations (phase separations, distillations, preliminary separations, etc.) as conventional sample-preparation techniques. In addition, the individual subsamples are described and the corresponding analysis is allocated to them. Only in this way is an unequivocal allocation of results possible in sample calculations and evaluation methods (and project).

7. Basic Functionality

The functionality of a LIMS is marked by five key areas:

1) Maintenance of master data
2) Order creation
3) Analytical processing
4) Management functions
5) Archive management

7.1. Registration (see Fig. 2)

Figure 2. Basic functionality of LIMS

The work flow in a laboratory begins with the *recording* of an order to examine an object. This

means a description of the object to be examined, by which it can be identified in the laboratory and used for the subsequent report to the orderer or for subsequent evaluation. The order (i.e., the required analyses, tests, etc.) is allocated to the object identified. Thus with the recording of an order a processing objective must be known. By means of the work order recorded, LIMS draws up the individual orders for the laboratories and work groups involved. The actual implementation of an order is adapted to the nature of the order so that the necessary operating sequence can be efficiently arranged:

Routine Record. With the aid of a routine sample plan, a task list is drawn up automatically from the master data. The registration can, therefore, be carried out by LIMS independently or by the user in confirmation of receipt of the sample (order). For sampling that occurs before the recording of the order, LIMS can draw up task lists for the samplers in advance of the routine sample plans.

Individual Record. Individual orders are recorded by the user, and at the same time master data are re-accessed and the order adapted to the requirement on the basis of the system's proposals.

All data of an order must be modifiable until processing is complete. The modifications must be performed by an authorized person and documented so that they can be understood later on.

7.2. Sample Distribution – Dissemination of Information

Labels, sample waybills, raw data forms, and assorted task lists for work planning can be printed with the aid of LIMS within the laboratory. However, the objective is to ensure the availability of information even without printed lists.

Information about the order, processing situation, and whereabouts of the samples of an order must be available through the LIMS to all those entitled to it. The samples are distributed to the working groups and LIMS upholds the checking of the samples' whereabouts.

7.3. Work Planning

The user decides on the processing sequence with the aid of the task lists drawn up by the LIMS. Since in most LIMS the master data base does not contain information on the capacity of the individual working groups and orders cannot be prepared by LIMS according to their actual processing (network plan), LIMS are not able to carry out independent operations scheduling. If analytical subsystems are attached, generally the person in charge must coordinate the loading of an autosampler between LIMS and subsystem. In principle though, methods exist for automatic sample identification by reading devices.

7.4. Recording of Results

The measurements are carried out and the raw data are recorded in the LIMS. In the next processing step, the LIMS calculates the results from the raw data. If several series of measurements exist, LIMS combines the results to give mean values and calculates the actual precision. The results are examined for their compliance to the range of application and precision as a function of the analytical method. In a further testing stage, the results are compared with expected sample-dependent values (e.g., specifications). Finally, after the completion of all testing stages, the results are released by the person in charge of the analytical method.

7.5. Validation

The results are subjected to a stepwise validation in the LIMS. Already during the first recording, the range of application, precision, and the desired object-related values were controlled. After the release of the individual results, a further checking step follows.

For this purpose, LIMS compiles the results produced at various processing units and tests these results for evaluations. The LIMS constructs the analytical report of the order from the combination of individual validated results.

At the general report stage a final validation occurs with inclusion of possible plausibility tests. In this stage, the LIMS notes the authority and responsibility of the user so as to eliminate unauthorized release.

7.6. Publication

The printout of completed (validated) analytical reports is automatically checked by LIMS. If a printout has to be distributed, then a centralized distribution is preferable to improve the handling efficiency. As distribution is manual the LIMS assists in sorting and copying reports according to requirements. The objective is also, in this case, to make results available to other receiving computer systems (process computers, administration computers, etc.) in order to avoid re-inputs of data.

Although LIMS allows the creation of the individual report as an exception, generally LIMS should produce reports in systematized style which can be reduced to four basic forms:

1) Summary
2) Standard report (e.g., according to EN45001)
3) Chronological survey
4) Survey by object (plant, product, etc.)

7.7. Archiving

After validation and release, the activity data from the order are converted into archive data and, therefore, withdrawn from any further editing. Herewith the analytical reports acquire document status. Direct amendment of these archived data (reports) is disallowed for documentation reasons. However, well-founded invalidity declarations for individual results and the nomination of new findings with appropriate authorization and justification are allowed. Recipients on the original distribution list of the report are informed automatically by LIMS of any correction (even authorized) of archive data.

7.8. Reserve – Waste Disposal of Samples

As specified in the order record, samples from processing are disposed of as waste or transferred to a reserve, which is also managed by the LIMS.

7.9. Addition to Basic Functions

The basic functionality of a LIMS has to be expanded for actual laboratory requirements. The processing paths described here are certainly adequate for most operations, but further requirements of the functionality are intrinsic to the management of samples during and after processing. An *expanded basic functionality* of order processing includes the correcting and annotating orders as well as assembling order and task lists according to various criteria. Further functions make it possible for the LIMS to produce compilations selected from the archive data and process them graphically. Through the use of interfaces, the selected data can be made available to other data-processing applications. The LIMS provides the user with means of creating reports and defining the reports' contents.

8. Expanded Functionality

8.1. Integration of Extraneous Programs

The compilation of results is followed by the evaluation phase. This means that the LIMS must be able to compile data which can then be processed in other programs. Such an interface is not restricted to the programs mentioned here (e.g., word processing, statistics, and graphical presentation), but is also necessary for integrating the LIMS into a data-processing environment extending throughout the company. Although the same basic approach is followed when integrating LIMS into a global data processing environment, complicated individual solutions also have to be expected.

The integration of a *word processing system* presents a special problem, since the analytical results are not subject to the same protection rules within the word processing system as within LIMS; i.e., they can be modified rather easily. This difference can be desirable, but it raises the question of the reliability of data taken over from LIMS in the outgoing reports. The recipient must therefore be able to distinguish between the different forms of report.

8.2. Cost Accounting

In the cost documentation on laboratory expenses, a LIMS can distinguish between personnel and material costs. The costs per "customer" are assigned through collection at cost centers which makes invoicing possible. Capacity utilization statistics for internal laboratory purposes can be generated from this accounting information. These statistics concerning costs, work load, etc., can provide a basis for medium-term investment decisions.

8.3. Inventory Management

Because all the necessary items of information are available from the order processing, LIMS can accept them into an inventory management system. LIMS continually offers an exact survey of the stock of reserve samples, of stock location, and the storage time.

8.4. Internal Quality System

The internal quality system controls the recording of reference materials and the proper use of analytical instrumentation, maintenance, calibration measurements, reference measurements, repairs, and purchases, etc. In this way LIMS ensures that only sucessfully checked analytical systems and methods are used for the processing of orders.

In addition, the stocks of reference materials and standards are maintained and managed within LIMS.

9. Adaptation of LIMS to Laboratory Tasks

If an electronic data processing system is to be introduced into an existing (laboratory) environment then it must be adapted to it. But since electronic data processing offers the possibility to perform new tasks and modify job processing, changes must also be made in the laboratory field for best utilization of LIMS.

Since the laboratory sequences are similar in all areas of industry, LIMS have developed as broard-based solutions. With similar central functionality, the differences when applied to different laboratory tasks lie particularly in the screen display layout, the logical data structures, and the functional complexity.

Therefore most of the laboratory requirements can be met by a ready-made system if its level of technical development is sufficiently high. A small proportion of the requirements can only be met with limitations; and an even smaller fraction of tasks requires actual changes or extensions. Slight adjustments within the screen display layout and functionality will now and then become necessary after operating experience.

Outline Solutions. After drawing up the performance specifications and examining the profitability, there are two alternatives for the introduction of LIMS:

1) Purchase of a ready-made system (and possibly then adapt)
2) In-house implementation

The purchase of a system must be preferred since, although in-house implementation certainly enables better adaptation to the requirements, it also entails a considerably greater risk. Besides, an individual solution is not subject to general development as a commercially available system. The standard solution demands compromises of the user. These are also necessary in the case of an individual solution, for reasons of cost and efficiency.

With the introduction of LIMS, the desired final state of organization has to be defined and compared with the present state in order to achieve the highest possible degree of systematization. Existing complexities in a laboratory environment are generally determined by past experience and resources and can, in all probability, be simplified or abandoned.

On average, two years are required to implement a LIMS for a medium-size application. Because of the complexity of the system, it is advisable to introduce LIMS stepwise in order to have a consolidation phase after each stage. Implementation can be done in three steps:

1) General LIMS introduction
2) Integration of analytical subsystems
3) Integration into the company's communication network

After the first phase, the LIMS functionality is available to the laboratory. In the second phase, operations are optimized by on-line recording of results. This concludes the adaptation of LIMS within the laboratory. In the third phase, areas outside the laboratory are integrated into the scope of the LIMS.

Adaptations. In principle, LIMS can be extensively adapted to the user's requirements. However, the adaption possibilities available to the user must be clearly distinguished from those available to the manufacturer of the system. In general the *user* can only adapt the system through arrangement of the master data. For the *system manufacturer* it is possible to make both adaptations conforming to the system (arrangement of the display surface) and changes of data structures and functionalities deviating from the system. A change of data structure and functionality can be equated to an individual approach. A LIMS with modified data structure and functionality is not subjected to general further development and maintenance by the manufacturer.

Systems originating from the use of powerful development tools are to be regarded similarly. The advantage here is the more probable minimization of the associated high risk compared with a new individual solution. With any individualistic approach, the future user and the system manufacturer need to be highly competent.

10. LIMS as a Component of Quality Assurance

Extensive responsibilities for documentation are imposed on the operator of a laboratory through the requirements of Good Laboratory Practice, an accreditation according to EN 45001, or in the framework of certification according to ISO 9001-3. A LIMS is basically not a quality assurance system, but rather an object to be itself safeguarded within such a system. That is, the LIMS must be arranged so as to guarantee the requirements of a testable mode of operation. However, within a laboratory a LIMS satisfies many quality requirements through the retention of master data necessary for the system and through the work flows specified by the system. Consequently, the LIMS considerably simplifies the observance of the quality requirements mentioned (and even makes them practically realizable from the expenditure perspective.

A version management of the entries can thus be carried out within the maintenance of the master data. With that, a methods and product archive, among other things, builds up. The handling of testing agents, standards, and reference materials is controlled and documented by LIMS. With proper application of the LIMS a task can be reproduced at any time from the recorded and stored data by reviewing the acquisition of results for an order and the associated decisions.

At the same time the LIMS ensures that in carrying out their duties all users always have the up-to-date information available.

11. Development Prospects

The main emphasis in the development of LIMS will be its further functional integration, into the laboratory itself and within the company. Project-related operating principles and control of the work flows are the main emphases of development in the laboratory. In production control, further possibilities for the laboratory are appearing in the automation of measuring procedures. The penetration of information and function throughout the company will involve the potentialities of a LIMS particularly in quality assurance, production control, and information appraisal. Further technical developments (hardware, standard software) are of secondary importance for the LIMS, since their result is not to develop the application per se of the system but rather primarily to improve its potential uses.

In addition to these lines of development, which mean an updating of the known system functionality, an innovative development step is conceivable. The LIMS, hitherto only passively recording and archiving data, can actively interpret data relationships on a structured knowledge base and consequently influence analytical procedures. Economic considerations will determine which of the directions of development will be favored. Of these, project LIMS, integration within the company, and aspects of quality assurance are emerging as the main points of concern.

Figure 1. The Kondratieff waves [116]
P = prosperity; Dec = decline; Dep = depression; R = recovery

1. Introduction

Since the invention of the steam engine in the 1700s, the world has gone through four long economic cycles, which were described by the Russian economist Nikolai D. Kondratieff (1892 – 1930) and are known as Kondratieff waves or cycles [115].

Each upward phase (identified as "prosperity" in Fig. 1) was borne by inventions such as the steam engine (Watt, 1769), the mechanized weaving loom (Cartwright, 1784 – 1786), the steam locomotive (Stephenson, 1814), the electrodynamic principle (Siemens, 1866), the diesel and Otto motors (1893 – 1897, 1876), and fundamental innovations in chemical process engineering such as the manufacture of basic chemicals.

The world economy entered another long upward phase at the beginning of the 1980s.

The development of the new basic innovation called "information technology", characterized by the invention of the transistor [117] and the subsequent rapid development of miniaturization and laser technology, but also by results from the field of informatics such as object orientation [118] and Petri networks [119], is described in depth in [120]. The economic boom identified with the new resource "information" [121] is a global phenomenon with heretofore unknown dynamic qualities. International business, national economies, and individual companies find in it growth and innovation potential that could scarcely have been imagined. Porter describes the importance of information as an essential resource for a successful corporate strategy [122]: *"The question today is not whether information technology has significant effects on a company's competitive situation, but merely when and how these effects will become apparent. . . . Anyone who does not react today will be compelled to follow a course that others have set."*

The fifth Kondratieff cycle, however, is not only an imposing technical and economic upswing but carries along with it profound social, ecological, cultural, and intellectual changes and challenges. These connections, often revolutionary in scope, were pointed out by Schumpeter [123].

The fifth Kondratieff cycle will render permanent changes in the way the individual thinks and acts and also into the strategies that corporations and national and international institutions will pursue. A technological advance will become a structural change [124].

Along with the classical production factors–energy, labor, raw materials, and proven production technology–information has become not just an additional factor but probably the most important factor.

CIM (computer-integrated manufacturing) and CIP (computer-integrated processing) are not merely slogans today [125]. Demands made by society, such as increased environmental awareness, better and more consistent product quality, improved delivery, and more econom-

ical management, necessitate production facilities and processes with greater flexibility and ease of operation.

Strategy, that is, the management of the company as a whole, means identifying goals and achieving them. Because a company's definition of goals must always be dynamic, it is important to inquire into what impact changes in the company's environment will have. As trends in sociocultural, ecological, technological, domestic economic, international economic, and politicallegislative settings become stronger and change more rapidly, optimal access to information becomes a central requirement for a successful strategy (e.g., in marketing, sales, and production).

But strategy also means making available the means for business success. An essential success factor is thus the exploitation of new information technologies based on engineering, physics, and information science.

Information is an unlimited resource that can be managed only if it can be structured. In the economic, administrative, and technical spheres, those responsible for information management must optimize the utilization of information by coordinating all parties involved and by creating a technical infrastructure.

The German term *Prozessleittechnik* (process control engineering) was coined at Bayer AG in 1980 as a working title covering the measurement, control, and electrical engineering groups [126]. The expression was chosen to denote the integral view of all those concerned with the management or control of production programs based on engineering processes.

Since that time, a number of events have made it clear that classical or signal-oriented measurement and control technology is being supplanted by information-oriented process control engineering.

Long discussions among experts regarding the terms "control" and "automation" came to an end when Lauber stated a valuable dichotomy, placing humans at the center of the analysis [127]: The role of humans can be (1) to specify the framework and the sequence of the process, which then runs automatically, or (2) to gain the maximum information about the process and intervene in it directly, becoming the agent that ultimately controls it. This question is discussed in more depth in Section 4.3. The authors of this article have a clear preference for the more universal term "control" and make use of various levels or degrees of automation (see also [128]).

"Essential impetus for development today is coming from information technology, which has become a significant tool in measurement and automation technology. Only information-oriented technology enables the industrial user to operate processes and plants in compliance with the criteria of flexibility, productivity, safety, and environmental protection. The integration of humans into the production process is of great importance if the operator must, for example, perform control functions at the interfaces with the automation system and with the process" [129].

The national and international standardization organizations of greatest relevance to process control engineering, such as the International Electrotechnical Commission (IEC) with its Technical Committee TC 65 and the German Electrotechnical Commission (DKE) have also replaced the term "measurement and control technology" with the new complex of "control engineering" (see Chap. 9). The Standardization Working Group on Measurement and Control in the Chemical Industry (NAMUR) had already announced such a new orientation in September 1987 [125].

The strong influence of information technology on automation technology and process control engineering is visible not just in the area of devices and systems (especially process control systems; see Section 5.2), but in all aspects of design, construction, operation, maintenance, and so forth (procedures) [130].

BASF has made their training programs in operational practice available to the public [131]. Detailed procedural instructions can be found in Strohrmann's [132] course on process control engineering (serialized in *atp* since 1984). Gruhn et al. [133] and Lauber [127] have published accounts of structuring practices for automation with an emphasis on process engineering and process computing automation technology, respectively. Töpfer and Besch have also described principles [134].

The time now seems ripe for attempting to present an integrated, information-oriented exposition of this subject.

The information structures employed in control engineering and the architectural principles

that generate them are therefore discussed and explained with practical examples (Chap. 2).

Next, the computational and mathematical methods used to acquire, reduce, model, and document process information are presented (Chap. 3).

Information about the process is used for process control (Chap. 4) by applying isolated and integrated control concepts and object-oriented process-control strategies (e.g., recipe management).

The control components of production plants, that is, the electrotechnical devices used for process control (sensor and actuator systems, process control systems including communication technology, process power supply, design of control and power distribution rooms and cable runs), are next analyzed from the information-technology point of view (Chaps. 5, 6, 7).

Computer-aided techniques (C-methods) have proved an especially useful information-technological support for the engineering of process control systems. General aspects of such systems and detailed structures of data-modeloriented design aids now in use or under development are described in Chapter 9.

The procedures used for the design, construction, and start up of process control facilities are set forth from a systems viewpoint and on a structural and sequential basis. Decision phases with the most important design document, (requirements and specifications) are clearly distinguished from execution phases. Quality assurance for the design, construction, and start up of process control systems is described in Chapter 10.

In the operation of production plants with process control systems, a change is taking place from signal-oriented man – machine communication to information-oriented, state-based man – process communication. This enables the plant operator to utilize knowledge about the process, formulated in an ergonomically correct way, to control the process. Continuous process analysis and process optimization take on new importance in this context. Strategies for maintaining or restoring the availability of process control functions are described in Chapter 11.

The standardization of process control techniques and systems in national and international bodies, societies, and institutions is presented in Chapter 12.

Finally, the integration of knowledge-based systems and modern concepts of fuzzy logic and neural networks are discussed in Chapter 13.

2. Information Structures in Process Control Engineering

2.1. Principles

Information as a Corporate Resource. In principle, information is an unlimited resource that can be managed only if it is structured. It is the task of information management to optimize the utilization of information by insuring the efficient interplay of all parties involved and providing the technical infrastructure.

The objective of information structuring is to reduce the degree of complexity by appropriate modeling (formation of data models and functional models) and thus create the prerequisites for information processing (input/output, storage, and analysis) by means of information systems. What has to be overcome, above all, is not the material but rather the inadequacy of the human intellect to deal with complexity.

The importance of adopting suitable structuring aids is demonstrated by the way in which technical, administrative, management, and logistical data "circles"–none, as a rule, consistent with the others–frequently come together.

Because they continue to be developed, application systems arise whose functionalities often overlap (Fig. 2, see next page) [135].

What is more, the demand for information depends very heavily on the level of automation present in individual production facilities. Production engineering systems often feature non-communicating automation islands. In fact, all such information circles are necessary, from the technical and economic standpoint, in order for the corporation to accomplish its task unhindered by departmentalization.

If information as a corporate resource is to be optimally deployed, it is essential to integrate information technology, and this can be done only when information concepts have been harmonized.

Figure 2. Convergence of isolated data "circles" and automation islands [135]

Integration of Information/Information Models and of Data/Data Models. Information integration is achieved by consolidating information across projects, leading to a mandatory corporate information model [136–139].

Such information models [140] are said to be "semantic" or "conceptual" because, at the user level, they reflect the definitions and interrelationships of concepts but not the realization of information in data-processing (DP) terms or the selection of information for specific applications. In contrast to earlier management information system (MIS) implementations, the result is an extremely stable information model. Appropriate representation techniques yield data from information and data models from information models.

Since 1970, theoretical publications on the form of such data models have been concerned chiefly with how the organizational problem of large data-base systems can be solved. For example, the mathematically grounded relational data model with its normal forms [141] was created first; the entity – relationship (ER) model, which stresses the semantic aspect of the data, came later [142].

In 1975, the ANSI/X3/SPARC DBMS Study Group introduced the "conceptual scheme", a comprehensive, implementation-neutral structure description of corporate information. This conceptual scheme is of central importance for the understanding and management of information systems [136, 143]; see also the SPARTEN information and control systems (ISS-$\alpha\alpha$) developed at Bayer AG [144].

Further detailed exploration and discussion of the conceptual scheme has taken place in the ISO Working Group with the same title. A detailed report is presented in [145].

Work on these aspects has continued; some results have been summarized and various methods, procedures, and tools to aid in the creation of data models have been set forth [146–149].

In the development of information systems, data properties relating to content, application logic, and organizational aspects are first examined in a "data structure analysis." The results must be described in a semantic or conceptual information model before the data model (which depends on the form of presentation) and thence the data-base design can be derived. The data-base design must take account of requirements and restrictions having to do with data-processing hardware and software. Restrictions based on processing considerations are brought in at another level.

The data-base design can thus be represented in a three-level model:

- Conceptual level: The result is the semantic or conceptual information model
- Logical level: The result is the logical data model, which contains restrictions having to do with data-base hardware and software
- Physical level: The result is the physical data model, which makes allowance for processing restrictions

A conceptual information model is constructed with an eye not to isolated information-processing functions, but to the objects of corporate information processing that are common

Figure 3. Methodological concept [151]

to all such functions. This is the strategic dimension of data modeling.

Such conceptual corporate data models are now being created in many companies. As a corporation-wide, application-neutral, implementation-neutral structural description of corporate information, such a scheme also constitutes the common linguistic basis for communications between persons involved in DP management. Because it is independent of the allocation of data among the company's computers, independent of physical data storage, and independent of the data-base systems employed, such a scheme can unify information systems based on a wide variety of hardware and software.

Integration of Methods. In the first period of software engineering, the software life-cycle model was in the forefront of discussion. Software development environments were designed in accordance with this philosophy. Alternative philosophies include rapid prototyping and participative system development [150]. Both aim at the early involvement of end users, whose acceptance is the single decisive criterion for the success or failure of an application system.

The appearance of data bases gave new impetus to the development of data modeling techniques. Because these are based on a variety of implementations, they are largely incompatible. For example, an elevator control system does not require a data-base design; an information system has no time-critical concurrent processes; and an expert system uses different knowledge representations from a procedural program.

If the data model has a hierarchical, network, or relational structure, different design methods are used.

An integrated methodology must generate both the data design and the functional design (Fig. 3).

It has often been overlooked that every design level of this methodological concept deals with a different aspect of the problem.

Thus, data and functional models are built up at the uppermost, conceptual level and then, in the further specification, broken down into a representation that can run on certain hardware.

Integration of Representation Means. The basic prerequisite for the common storage of design data and the transfer of information between methods is an appropriate representation form.

Today, graphical and textual representation means can be thought of as being diametrically opposed.

Each, however, has its justification. Graphical means of representation (flowchart, function diagram, entity-relationship diagram, polling hierarchies, etc.) are a suitable idiom for use in the human – computer interface (Table 1).

Textual means of representation (pseudocode, structured text, computer languages of various generations) yield expressions that are understandable chiefly to the computer.

Table 1. Methods and their points of emphasis [152]

Method	Points of emphasis
Structured Analysis (SA)	Representation of functions, data regions, interfaces, and data flows connecting them, in the form of hierarchically organizable nets
Structured Design (SD)	Representation of modules and their interfaces in "Structured Charts" and module level model
SADT	Representation of functions, as well as data and control flows connecting them, in the form of hierarchically organizable nets
Entity-Relationship Model	Representation of objects and their quantifiable relations (1: 1, 1: n, etc.) in the form of nets
Decision Tables	Representation showing under what combination of conditions certain actions can be performed, in the form of tables
Finite-State Automata	Representation of states and state transitions, and also of inputs initiating changes of state as well as outputs initiated upon changes of state, in the form of nets
Petri Nets	Representation of states and events in the form of nets whose behavior can be dynamically investigated with the aid of the Petri net rules
ISAC	Representation of information sets, as well as information flows and functional sequences, in the form of seven types of nets
Jackson Structured Programming (JSP)	Representation of the data structure of a problem, derivation of the program structure from this data structure
Jackson System Development (JSD)	Representation of objects and their actions in the form of trees, and of the connections between objects in the form of nets
MASCOT	Representation of processes (and devices) and their communication regions in nets
Functional nets	Representation of processes and devices as well as their communication, in the form of nets
HIPO	Tree-type breakdown of a system and definition of every part in terms of input and output data and required operations (steps)

There must therefore be a way to translate between graphical and textual means of representation.

The task remains to harmonize these means of representation with one another, obtaining a canonical set of description means that can be used to describe data structures and functional structures with regard to both static and dynamic properties.

Integration of Tools. The most important tools for data integration are data-base systems and data dictionaries [138, 153].

In order that the data in a data base will represent a consistent system of facts, the permissible and necessary relationships between data are specified by means of integrity conditions and monitored and controlled in real time by a data-base management system. Data-base systems offer a range of concepts that support "information management."

In particular, these include concepts for modeling and manipulating data in an application-oriented fashion (data models), for integrating various applications over the same data base without redundancy (data integration), for making an application neutral to changes in the logical and physical organization of the data (data independence), for insuring data consistency, multiuser synchronization, and data security, and for safeguarding the stored data against unauthorized access.

A data-base system is said to be of hierarchical, network, or relational type, depending on the underlying data model.

Hierarchical and network data-base systems have become established in commercial, administrative applications. Relational data-base systems are gaining ground in engineering applications, such as the support of design processes (in the design of mechanical parts, LSI circuits, process monitoring and control equipment, and software development) and process control. Distributed and object-oriented data-base systems have not yet become widely available from commercial sources.

In contrast to data-base systems, a data dictionary is a system for storing and processing data definitions (data descriptions) for one or more software systems. In its simplest form, a data dictionary can be regarded as a well-organized notebook containing basic information about all the data elements stored in a computer for an application area [154–156].

These support not only a one-time, uniform, consistent documentation of information objects, but also the management of other objects used in the DP environment (such as jobs, projects, users, etc.) as well as their relationships. Data dictionary systems are themselves data-base systems that use a central data base to manage all information needed to describe, pro-

cess, and use the objects of an application area, regardless of their internal organizational structure. Data dictionary systems also support data management for application systems and thus contribute to the efficient development, implementation, and description of software systems.

A number of other tools have been devised in the course of the software engineering discussion. Each of these tools is suited to a certain class of problems; each either extends over multiple phases or is specific to one phase [140, 157, 158].

For example, editors are for the creation of graphics and texts for use in a variety of methods; compilers, linkers, debuggers, and so forth, for the implementation phase; test tools, for the testing phase.

Tools for retrospective documentation are becoming more and more important at present.

Decades of software development have produced software systems that can scarcely be maintained any more (the "software crisis"). The documentation of these systems is often in a wretched state.

Because of changes in methodology, it is no longer sufficient to document such systems in the context of their own (usually obsolete) approach. What should be aimed for is to create new documentation for old systems, with an eye to future trends in software engineering.

Retrospective documentation is a more and more pressing need in a management context, where decades' worth of investment in software must be safeguarded. This does not necessarily mean that obsolete software systems must continue to be used in their existing form. The minimum requirement is that the information and technical knowledge contained in the system must be revealed and made accessible for new developments.

The integration of tools means that documents can be passed along from phase to phase and from tool to tool.

Integration of tools can succeed only if information, data, and methods have been integrated. This applies not just to all engineering activities during the lifetime of a technical device (see Chap. 10), but also to the design of monitoring and control equipment itself, especially of process control engineering systems (see Chap. 7).

2.2. Architectural Principles for Information Structuring

Systems and Architectural Principles. Real-world systems and elements have internal structures. Along with Aristotle's doctrine of categories [159], the Linnaean system–still a valid descriptive model employed in botany–provides an example [160]. Darwin's ideas on the origin of species [161] also illustrate this structuring process.

In the 1700s, "system" at first meant a collection of linked truths. The links had to be methodologically correct and completely deducible from an underlying principle.

KANT's concept of system stresses the theory of systematics. In his "Critique of Pure Reason," he emphasizes the significance of architecture as the art of systems.

Thus a system, traditionally, is a closed whole whose parts are interrelated, interact, and satisfy certain constraints.

The parts, regarded as elementary, are called elements of the system. A system consists of elements with properties; the elements are structured and linked together by the relationships in accordance with a system principle. Systematization involves specifying system principles and devising system structures. Systems are characterized by the fact that they have properties that cannot always be accounted for by the properties of their elements. Thus simply collecting elements does not form a system. Instead, each system has a structure that is generated by the relationships among its elements.

Systems can be subdivided into parts on as many levels as desired, whereby all parts that are not elements of the system are referred to as subsystems. System elements are the parts of a system whose further subdivision is impossible or undesired.

The sections that follow state principles for the structuring of information. They are called architectural principles because they can be identified at various points in the design process and in various representations of the information system, thus marking the architecture of the information system. The first principles discussed are general ones in the phases of design and implementation.

Principles in the "definition of requirements" phase, quality assurance in parallel with other

activities, and operation of a facility might be added here. These are also referred to as con-struction principles, since they are applied mainly in the construction of DP systems.

This is demonstrated by the example of modern operator interfaces, where structuring of information is used to support human – process communication (see Section 11.2).

Higher concepts of functional and data structuring also make use of the design principles discussed above but represent a more application-oriented aspect of structuring.

The focus is on the object-oriented formulation, which can be applied to both functions and substances [162] in an integrated methodological concept. It is the tool for the decomposition principle, with which complicated objects are broken down into their constituent parts.

The next most important structuring principle is abstraction, which is a fundamental approach to concept formation. Adopted from expert-systems technology, abstraction is introduced as a construction principle of application systems through class-forming, concept-forming, complex-forming, and functional abstraction. Closely related to the principle of abstraction is that of inheritance [163–165].

The last section deals with transformation principles. Here the various models used for problem-solving are described, starting with procedurally oriented formulations (with their counterpart in functional design) and passing through logic-oriented formulations (as now employed by many expert systems) to state-oriented or event-oriented concepts (which come much closer to process-related DP problems).

State-oriented and event-oriented formulations in turn are closely related to object-oriented ones. Objects are in certain states and communicate with one another via established protocols (see Chap. 8).

The complexity of present-day systems increasingly calls for a holistic, network style of thinking [166, 167] if the basic laws governing systems, their dependences, and their interac-

Figure 4. Design principles

tions are to be understood. It will take a new kind of thinking to comprehend the dynamics of a continuous process, plan a monitoring and control system for it, erect and operate the system, employ higher-level information systems, and in the process not overlook human beings [168].

The Decomposition Principle.

Design Principles. Structuring principles occur in all phases of system development. In the design phase, for example, the top-down and bottom-up principles are often encountered. In the top-down approach, a whole is broken down into parts step by step, whereby the complexity of the parts under consideration is systematically decreased (decomposition principle).

In bottom-up design, single parts are assembled step by step and made into a whole.

In practice, mixed forms are often encountered (Fig. 4, see previous page).

Bottom-up design comes into play when prefabricated elements are available from which the overall systems can be assembled. This principle is often used in mathematical and statistical applications, where the elementary mathematical and statistical functions are known and can be made available in program libraries. New applications can be analyzed only by the top-down approach, though there is a trend toward reusable elements here too (see, e.g., Section 4.5).

Implementation Principles. The implementation phase also exhibits principles that ultimately determine the structure and thus the understandability and maintainability of software systems.

The more ordered the structures are, the better they lend themselves to verification, modification, and maintenance. The simplest ordering is linear. Iterations, recursions, and branches generate more complex structures (Fig. 5).

Recursive data and functional structures are preferred today because of their mathematical compactness. It can be shown, however, that iterative and recursive structures are equally powerful and can be transformed to one another.

Another type of structure is the directed tree with strict hierarchy or polyhierarchy, which ultimately becomes the general network if the rigorous requirement that every node has only a single input is dropped (Fig. 6, see next page). The last is especially important in so-called master–slave structures. The slave should have only one master, since otherwise there can be conflicts in execution. Ring and star structures form a separate class.

Figure 5. Types of structure

Principles for User Interface Design. The user gains access to the system through the user interface. A number of structuring principles apply to this interface, not all of which can be discussed here.

Design principles such as the law of like form, the law of color, or the law of proximity (Fig. 7) should be employed in the layout of masks and printouts [169, 170].

Principles such as conformity to expectation in dialog with the system (also called "principle of minimum surprise"), consistency of dialog elements, and visualization of the application context also play an important part.

Modern software ergonomics focuses on job design for people, a process that is heavily influenced by software [171, 172].

An important goal in software writing must be the design of complete activities. A complete activity has been defined as an activity that, to-

Figure 6. Types of tree and network structure

gether with simple execution functions, includes the following:

- Preparatory functions: identification of goals, development of procedures
- Organizational functions: agreement with other workers as to tasks
- Monitoring functions: feedback to the worker on attainment of goals

Incomplete activities are activities where there is essentially no possibility of independent goal identification and decisionmaking, no scope for individual ways of performing tasks, or no adequate feedback. Shortcomings in job design impair the motivational and learning potentials of the work process and affect the worker's welfare and job satisfaction. Intimately linked with the completeness of activities is the degree to which the worker has opportunities to make decisions as to time and substance, that is, freedom of action.

This freedom of action must permit creative users of an information system to devise an individualized procedure in accordance with their experience and working style. At the very least, defining freedom of action should not be part of the program author's responsibility; it is a function of corporate management and personnel practices. Observed acceptance problems often stem from misjudgments in this area.

Figure 7. Simple design laws [169]

A new type of human – computer interaction has come into being with the new class of workstations. This user interface has the new feature that it presents the user with graphical images of customary objects belonging to the office world. Such objects can be selected and then manipulated with the aid of a pointing device (mouse, light pen).

SHNEIDERMAN [173] introduces "direct manipulation" as a collective term for several new principles in the user interface. The most important principles are the following [174, 175]:

- Permanent visibility of the object as an icon or pictogram
- Quick, reversible, one-step user actions with immediate feedback
- Replacement of complicated commands with physical actions (see also Section 11.2)

Higher Concepts of Functional and Data Structuring. Historically, the functional structuring of application systems was emphasized in the early period of data processing. A complex function was successively broken down into partial functions until elementary functions realizable in DP hardware and software were arrived at (flowcharts).

Data were fitted into the functional structure but remained meager, as they had to be given in the programming languages known at the time.

The structuring principle was oriented to the procedure employed in problem-solving. As a result, functional structuring led to process-oriented or program-oriented structures (Fig. 8, see next page).

Even today, functional structuring is still the classical approach, because it leads directly to realizable, procedurally-oriented solutions. At Bayer, for example, all engineering tasks were modeled by the SADT method, somewhat as shown in Figure 304. [177, 178].

Thus the modeling concept (functional structuring) and the implementation concept (procedural programming language) correspond.

Data structuring is of secondary importance: What is interesting is the processing of the data, and data-base systems were not yet in use at this time.

However, functional structuring has several weaknesses:

- There are scarcely any objective criteria for breaking the function down into partial functions. Decomposition is often a matter of the developer's discretion.
- The resulting data structures unavoidably grow out of the functional structure and are monolithically bound to it. Any change in the

Figure 8. Functional structuring for the example "develop software" [176]

data structure impacts on the functional structure, and vice versa.

– Frequently, insufficient stress is laid on reusability, since it cannot be known how and in what connection an arbitrarily defined function or an arbitrarily defined module may be used again–in contrast to mathematical and statistical program libraries, where reuse is straightforward. The complexity of such a DP system increases more than proportionally to the functionality.

In the early 1970s, greater value was accorded to data structuring. This was the period of developments such as the PASCAL programming language and the first hierarchical data-base systems. Data structuring became more important.

Subsequent development is marked by attempts to shift the meaning of the data (the infor-

Figure 9. Structure of PCE propositions

mation) out of the programs and into the stored data, and to generate program systems in a manner directly opposed to the functional approach. Now the first step in system development is to design the data model on which the later program systems will work.

One speaks of data-oriented or object-oriented structuring, since the analysis is focused on information objects (data structures) as representations of real or abstract objects.

Objects are described and related to one another through their properties, also called attributes. Typical relationships are abstraction and mapping (correspondence) relationships [137].

The result of this approach to structuring is the semantic data model, which is designed independently of the functions defined on it [146, 149].

In his epistemological discussions, Wendt [147] classifies objects as concrete and abstract. Concrete objects include things and processes; abstract objects include concepts (see [162] and Fig. 9).

After the existence of objects and the properties of objects, the relationships of objects are taken up third. A first type of object relationship is described by ordering, which is arrived at through a comparison of some property.

Other important object relationships are part-whole relationships and instrumentality relationships. An instrumentality relationship is said to exist between a thing (e.g., a process facility, a process monitoring and control system) and a process (e.g., a continuous process, a control process) if the thing plays a part in the process.

Inseparably connected to processes are states. States include the initial and final times of processes or subprocesses.

If countability is associated with the concept of object, and measurability with the concept of property, then the concept associated with the concept of relationship is decidability [147]. Objects are counted, properties measured or described (see "Scales" in Chapter 3), and relationships are decided.

Thus the three fundamental concepts – object, properties, and relationship – have been introduced. These make it possible to structure experience, and thus they govern the world of human thought [147, 179, 180].

Concrete objects are the plant, the apparatus, the process monitoring and control system, the production process, the reaction process, the sensor – actuator process, the data-processing process, and so forth. This group of objects is also called "devices"; devices must be designed, built operated, maintained, and optimized, these activities being known as "procedures." The outcomes of these procedures are represented as flowcharts, construction drawings, process monitoring and control station diagrams, and so forth. In the Cassirer scheme, both groups of objects are called substances. Functions that describe a task or activity (e.g., plant/apparatus coding; see Section 2.3) also have a representation in the object-oriented formulation (see Figs. 23, 25, and 65).

Functions (i.e., tasks) are implemented through procedures (abstract objects) from devices (concrete objects). Figure 9 gives a large-scale survey of "object worlds." For clarity in terminology, relationships are described not with the function concept usual in informatics, but with the epistemologically based relation concept (cf. entity relationship) [162].

The abstract representations are the objects that can be manipulated in the computer. They always relate to an object, which they describe from a certain abstract point of view.

The object-oriented approach thus represents a "natural" modularization concept, since the objects can be extracted directly from the application. If the functions are likewise structured in an object-oriented manner, this constitutes a principle of functional structuring that is far less sensitive to modifications.

The Principle of Abstraction. The (provisionally) last step in development combines relational and object-oriented structuring. In the "abstract" data type, data structures and relational structures are merged into a whole. The relations enclose the data as if in a shell; the data can be manipulated only through the relations "guarding" them. The high modularity of these constructs suggests that there may be significant gains in the reusability and maintenance of software. This principle is referred to as data encapsulation or "information hiding" [165, 181–183].

The structuring principle is thus concerned with the structuring of data and relations, their (static) structural and (dynamic) sequential structures, and their interactions.

Usually, the sensory or empirical view of things is said to be "concrete," while any description in terms of concepts is said to be "abstract" (see also [147]).

Abstraction means reducing complexity by neglecting all inessential properties or features. One also speaks of models.

Models are always simplified pictures of the real objects (abstractions) as viewed from a certain aspect (see also Sections 3.1 and 3.3).

In process engineering, flowsheets are models of a real facility in graphical form. They are standardized and represent the medium of communication for persons involved in the design, construction, and operation of plants (Fig. 10).

Mathematical models in the form of systems of algebraic and differential equations depict partial aspects of the physicochemical and apparatus-specific parts of processes. Such models are used, for example, in model-aided measurement techniques for the control of processes, the detection of faults, and simulation (see Chaps. 3 and 4).

A plant model is a representational picture of the plant that is much favored as an object of study by plant designers and operators.

The three-dimensional representation of plants in CAD systems is a way of getting the advantages of such models while using only DP resources.

Along with mathematics, the field of informatics now offers methods with which complex engineering systems can be modeled, simulated, and optimized.

It must not be overlooked that data models are always reductions from real systems. Models, no matter what kind or in what medium, represent a given system from various points of view. They emphasize essential properties and suppress inessential ones. Within these limitations, however, models are an indispensable part of any modern information technology.

Class-Forming Abstraction. Object orientation means that once the objects have been identified, they are then described in terms of their properties or attributes. Each such property consists of a category and a value; these can be scaled either metrically or nonmetrically (see Section 3.1 and Fig. 40). The number of properties describing an object is not intrinsically re-

Figure 10. Design steps in process engineering [184]

stricted. The treatment is generally limited to the attributes relevant to a mode of examination or an application, or to characteristic attributes; this is equivalent to an abstraction (Fig. 11). Such attributes can be listed in a table (Fig. 12, see next page).

One column in the table describes one characteristic property or attribute of the object. The table represents a "class of objects"; that is, a collection of objects having at least one attribute category in common.

The attributes describing a class simultaneously identify the type of an object. If the same attribute categories are employed for the description of more than one object, these categories are said to be "generic."

Figure 11. From things in the real world to abstract objects

Instances of object class "plant"

Figure 13. Instances of a class of objects

A given object in the real world is called an instance of the class (Fig. 13). The concept of table, also called relation, leads to the relational data base, which utilizes the relation (= correspondence, dependence, etc.) as its organizing principle. The table as a data structure is purposely not given any further structure, so that it is possible to create a "relational algebra" that is mathematically well-defined. Any manipulation of the data base is thus broken down into set-theory operations.

Apart from class-forming abstraction, the identification of objects is important. Each instance of a class must be identified by a unique name and/or a unique identification number.

Without exception, every one of the classification schemes devised earlier for identification purposes has failed, because objects cannot be unambiguously classified (see Concept-Forming Abstraction) and an excessively narrow decimal classification system often proved too restrictive. Classification systems were weak forms of data modeling at a time when data bases and semantic data models were not yet known.

What is recommended today is an unsuggestive, system-free, numeric or alphanumeric code and the description of properties–including the membership of the objects in one or more classes (polyhierarchy)–in a semantic data model.

Another form of identification has been discussed in connection with direct manipulation. An object is identified by "pointing" at it. This principle of identification is extremely important for the ergonomics of user interfaces (cf. the icons first introduced by Apple in the Macintosh). A third option is to describe objects so that they can be found again. The relational data base draws its strength from this approach. Structured query language (SQL) represents an industry standard and makes the results independent of the data-base system.

Concept-Forming Abstraction. Concept formation is an act of abstraction that leads to concepts and hierarchies of concepts. It is a generalizing process, in which particulars are disregarded. Unimportant properties of the object are left out; those remaining govern the class of the objects. Each abstraction rests on a certain objective of thought or speech, for example the objective of being able to think or speak about [179]:

- Things, regardless of engineering details
- Procedures, regardless of what principles or concepts apply to them
- – Factual statements, regardless of meaning-preserving transformations in the form of circumstances

According to Frege [185], things that are already linguistically available are grouped, from the viewpoint of something they have in common, into a "concept," which offers an invariant way of speaking or thinking about things already linguistically available.

The formation of "abstract" concepts cannot take place in isolation from the intended purpose or objective. This may be a disadvantage if one wishes to do modeling in the most application-independent way possible at an early stage of system design. For example, a biologist might group dogs and cats together as domestic animals, place these in turn under mammals, and so forth, while a jurist might distinguish movable and immovable objects simply because movable objects can be stolen and such taking is a statutory offense. Darwin, in "The Origin of Species," had already discussed the difficulties involved in devising consistent taxonomies and hierarchies of concepts [161].

The concept arising from concept formation is not specified in advance but lies in the discretion of the data modeler. It is therefore quite possible for multiple taxonomies to exist in one and the same realm of objects. This can be illustrated by a simple example: If one abstracts from the manufacturer of certain bimetallic sensors, the concept or class used is that of manufacturer, while the concept introduced is that of bimetallic sensor (Fig. 14 A; see also [186]). If one wishes to introduce the concept of expansion sensor along with the concept of bimetallic sensor, there is a further abstraction process using the principle of measurement as class (Fig. 14 B) and leading to the more abstract concept of temperature sensor.

Now it might occur to one to set forth the sensor program in closed form by manufacturer; now the taxonomy looks different again (Fig. 14 C; see also Chap. 5).

Complex-Forming Abstraction, Aggregation. In complex-forming abstraction, unlike objects are combined into a new object-concept. The process is also termed aggregation, because the new concept denotes either the static structure of one object or the relationship between objects. The object newly created by aggregation can also have new attributes that are made possible only by the new whole. A distinction can be made between this operation and agglomeration, a simple collection of objects in which the attributes present merely change in value.

Aggregation can also be represented in graphical form. Figure 15 A shows the static structure of a sensor system. The concept "customer order" (Fig. 15 B), on the other hand, is constructed from the concepts of customer, article, and time. The new customer order concept contains part of the information from each of the original concepts [148].

Quite early DP programs were able to handle aggregation in the form of parts lists.

Functional Abstraction. A system can be modeled in greater or lesser detail and in a more or less abstract fashion, depending on the objective. Different persons, with different tasks and areas of responsibility, take different views of the system. Systems analysts and system modelers always describe a system as an excerpt of reality viewed from one or several of these standpoints. According to Polke [168] (see Fig. 29), Rasmussen introduced systematic order into the more-or-less intuitively grounded models [187], describing a system (Fig. 16) as functional ab-

Figure 14. Taxonomies of sensor systems
A) Abstraction according to manufacturer; B) Abstraction according to measurement principle; C) Alternative taxonomy

stractions over multiple levels. The number of levels can differ from one system to another, depending on the type of system and the objective. Nor do all the levels have to be implemented. The design levels of this model extend from intensional models at the uppermost level to extensional ones at the lowermost.

Extensional models relate to the specific physical world, while higher-level models represent the purpose and objectives that are to be achieved with the system.

Scales for the desired behavior must to be developed from the purpose of the system; in other words, criteria for errors and malfunctions can be formulated only against the background of the process objective.

In certain operating states, for example, alarms may be meaningless; measurement signals may have different nominal and limiting values, depending on the operating mode; and so forth. The causes of errors or malfunctions arise from the physical world (bottom-up), while the criteria for defining errors can only be derived from the process goals (top-down).

This approach to modeling brings order to the great variety of representations of a system.

Figure 15. Examples of aggregation
A) Structure of a sensor system [232]; B) Complex object: customer order

Figure 16. RASMUSSEN's scheme of viewpoints [187]

Above all, it demonstrates that no single representation is adequate; a different view of the system may make a different representation useful.

Many technical and economic systems have been created under this architectural principle. Typical examples are computer architectures; architectures of communications equipment, the latter known as the ISO-OSI reference model (e.g., [188]); and the level model of a corporation discussed in Section 2.3 [168, 189]. The structures of monitoring and control systems men-

Figure 17. Hierarchy of functions (level model)

tioned in DIN 19 222 also fall under this principle [190].

The principle of functional abstraction is based on the following rules:

- The levels must offer generally usable functions and relations; that is, they must represent a good abstraction.
- The levels must have clear interfaces and minimal upward and downward connection; they must obey the secrecy principle.
- They must completely implement the required functions; that is, they must be self-contained, with the properties of locality and internal strength.
- A level "uses" the services of the level immediately below it. Jumping over levels is not permitted.

It follows that all functions requiring intensive data exchange with one another should be grouped on the same level (Fig. 17).

The design process for engineering systems is also oriented to such a level model. For example, mechanical design begins with the functional structure, proceeds through the operative principle of design synthesis, and finishes with dimensional synthesis.

The Transformation Principle. In chip design, the following levels are recognized: system design, logic design, circuit design, and layout design. The process makes use of detailing algorithms.

Configurable detailing algorithms are not known for the corresponding steps in plant design based on flowsheets (Fig. 10).

If the design process within a process monitoring, control, and automation system is to be completely or partly automated, it must be clear above all how the representation form of one design level is to be transformed into the representation form of the next one. For the developer and designer of an automation system, such a concept supports creative design activities, design verification, project planning, and documentation.

This transformation process in informatics is fully automated by problem-oriented languages, assemblers, and on to machine code. Programs that do these transformations are called compilers, assemblers, and so forth.

Sequence-oriented description concepts and representations are required in order to describe the functions of information-processing operations. One speaks of a transformation principle because input data are transformed to output data and initial states to final states.

The following description types are distinguished on the basis of how the operator is implemented:

- Sequence-oriented descriptions
- Logic-oriented descriptions
- State-oriented descriptions

Sequence-Oriented Descriptions. Classically, information-manipulating processes are described in terms of individual, application-

neutral elements. It can be shown that any routine or any procedure can be described in terms of the linguistic elements sequence, alternative, and iteration. In a procedural programming language, it would therefore be sufficient to make these three constructs available.

Typical graphical descriptive media for procedural concepts include

- Flowcharts
- Nassi – Shneiderman diagrams
- SADT diagrams
- Michael Jackson diagrams

Textual media include, among others,

- Pseudocode
- Structured text
- Programming languages such as FORTRAN and PASCAL

The analogy between operators in mathematical physics and their importance in the description of state changes (including time-dependent changes) can only be mentioned here [191].

Logic-Oriented Descriptions. Logic-oriented concepts relate not so much to the "how" of the process as to the "what." Graphical media used for this purpose include

- Combinational circuits
- Logic diagrams
- Decision tables

Textual media include

- Fourth-generation languages
- Algebraic specifications
- Logic-oriented languages

State-Oriented Descriptions. The automation of technical systems often requires the control of processes that take place in a predominantly step-by-step (i.e., discrete) fashion. The complexity of a discretely controlled system becomes very high when there are processes parallel in the time domain (i.e., concurrent processes). If these processes use shared resources, there is always the risk of "deadlock." The processes block one another in such a way that they cannot continue to operate without outside intervention. Such deadlocks cannot easily be foreseen. The need for an analysis and, possibly, a simulation of these systems is thus manifest (compare the typical situation of management in a multi-project environment [192]).

Such problems can be described well in terms of mechanisms or automata.

A finite-state automaton is a system having a specified number n of possible internal states $z_1, \ldots, z_n$. For each state z_i there is a well-defined set of inputs for which the automaton changes to another state. An output can occur when such a transition takes place. Automata can be used to describe the time order of state transitions in technical systems.

State graphs (Fig. 18), with circles for states of the system and arcs for transitions between states, are used to visualize these systems.

Figure 18. State graph illustrating an automaton

In practical cases, however, the number of global states increases rapidly, so that the representation of the time order by state graphs becomes unwieldy.

The Petri net, an extension of the state graph concept, offers a more elegant way to describe such systems.

A Petri net is a directed graph whose nodes are of two types, places and transitions. Arcs, which can connect two nodes only if they are of different types, represent logical or causal relationships between nodes [172, 193–201].

Using a mode of analysis different from that of state graphs, the Petri net technique allows the description of systems that represent more extensive automata. Thus, the circles (places)

represent partial states in the system and, therefore, conditions for the occurrence of certain events that can occur in the system and lead to state transitions.

The partial state represented by a place is in effect if the place holds one (or more) marks or "tokens."

A transition is enabled, that is, it can occur or "fire," when all its input positions (arcs leading to the transition) have tokens while all its output positions (arcs leading away from the transition) have none (Fig. 19 A).

Figure 19. Petri net with initial and subsequent markings and the associated reachability graph

When an enabled transition fires, tokens are removed from its input places and placed on its output places, which now may enable transitions in their turn. In larger nets, this rule means that several transitions may be enabled at once; this is known as concurrent execution (Fig. 19 B and C).

A Petri net lends itself not just to graphical representation but also to mathematical description. On the basis of such a description, the dynamic behavior of the net can be studied by using computer-aided analytical tools.

Interesting properties of the net include, for example, reachability and the presence of deadlocks: If each possible occupation of the Petri net with tokens (each "marking") is interpreted as a possible global state of an automaton, the associated state graph is also called a reachability graph. It immediately shows whether there are markings of the Petri net that can be reached in just one way or cannot be reached, whether there are deadlocks, or whether the initial marking can be reached again (reversibility; see Fig. 19 D).

Petri nets can be broken down in hierarchical fashion and so support top-down and bottom-up design.

In the area of process control, Petri nets are usually represented by functional charts. The technique of functional charts makes it possible to portray directly the structure of a Petri net and offers linguistic elements for the specification of control commands to be issued at the individual steps (nodes of the net).

One graph that is especially easy to comprehend is the "phase model" of production, which is discussed in more detail in Section 2.3.

2.3. Applications in Process Control Engineering

Object Worlds of Continuous Production Processes. If the system to be designed or operated (whether it is an apparatus, a plant, a control system, a software system, or some other system) with all its subsystems and components is placed at the focus of computer support, the monitoring and control of continuous processes can be broken down into plant engineering, process engineering, and process control engineering worlds.

In order to describe the actual operation, these are supplemented by the world of process communications, logistics, and maintenance (Fig. 20) [202].

Figure 20. Object worlds of continuous production processes [202]

In an object-oriented approach, substances in these worlds can be defined as functions. They represent the uppermost level of a corporate data model within process control engineering [198].

Plant Engineering. Typical descriptions in the field of plant engineering take the form of data sheets (Fig. 21, see next page).

The abstraction principles discussed in Section 2.2 can be seen in this data sheet: The glass-lined stirred tank, as represented in Figure 22 (page 27), consists of drive, clutch, stirrer, tank, stirrer shaft, shaft seal, motor, and gearbox (complex-forming abstraction, aggregation).

Some of the objects are further specified; for example, the stirrer is identified as an impeller, dual-impeller, or anchor type, and the stirrer shaft seal is specified as a stuffing box or a rotating mechanical seal (concept-forming abstraction).

All objects listed on the data sheet are described by a series of attributes and thus stand for a class of objects (class-forming abstraction).

The "plant and apparatus coding" (PAC) scheme can be viewed as a first formulation and crystallization point for a corporate data model [203]. This coding system describes the static structure of a plant in terms of the required functionality (Fig. 23, page 28). It has analogies with the "power plant coding system" [204].

While most description systems do not separate the functions (tasks) of a plant (abstract) from the real technical plant (device), the PAC gives a rigorous description only of the function, up to the technical device and its functional components, and is therefore invariant to actual technical implementations (Figs. 23 and 65).

Earlier DIN representations [205] could not employ the object orientation logically utilized in the implementation of the PAC [203].

For this reason, stress must be laid on the worldwide harmonization of concepts; this comment applies equally to all three of the "object worlds" under discussion here.

Process Engineering. The following example of process engineering illustrates a taxonomy of unit operations (Fig. 24, page 28) [206].

The classification scheme first looks at the most important operations, such as separation, combination, and so forth. The next criterion applied is the state of aggregation of the starting material (see also [207]).

The general production instructions for the making of a given product (Fig. 25, page 28) also arise from process engineering.

While the first attempts to formalize production instructions were based on the classical structures of thinking in process engineering [208], more recent approaches start with the phase model of production derived from the

transformation principle [209]. The configuration principle of modern process control systems builds on knowledge from object-oriented programming and, more recently, experience in modularization [210–212]. Figure 26 (page 29) illustrates the correspondence of plant model and process model (see also Fig. 65).

Process Control Engineering. To illustrate the relationship between process engineering and process control engineering, consider what happens in the transition from a generally valid recipe for making product A to a recipe for making product A in plant X. In a taxonomy of recipes, this is a concretization of the "plant-independent" basic recipe into a plant-dependent control recipe. New research by the ISA, particularly on the topic of batch control systems [213], and by NAMUR-AK 2.3 on requirements for recipe-mode operation [214] must be taken seriously as a basis for discussion. Figure 27 (page 29) illustrates the principal recipe types [214].

If one assumes a self-contained recipe for the individual operating modes (see Fig. 123), the taxonomy of recipes shown in Figure 28 results (see page 29).

Level Model of a Corporation. Structuring by hierarchical levels (functional abstraction) is encountered in a variety of forms (e.g., for the description of computer networks or data bases). A corporation can also be represented in this way.

According to a suggestion made earlier [189, 215], if the abstraction principles stated above are applied to a corporation, four levels can be identified. By way of example, Figure 29 shows schematically a model of a company involved in the process industry. The four levels are the corporate management level, the production management level, the process control level, and the field level. The dispositive quality of the functions decreases from top to bottom, while the operative quality increases.

In what follows, the corporate, production, and process control levels are discussed for the production division of a chemical industry corporation [168, 216].

Corporate Management Level. In a world where increasing competition demands rapid and often massive reactions in many markets, the corporate management level, where goal-setting and long-term planning are done, is becoming more and more important.

The key condition for the support of the corporate management level, once systems-engineering problems have been solved, is effective control of the lower levels, in particular the establishment of conceptual information structures.

For this purpose, the information available on the subordinate levels must be compressed in a way appropriate to its use. A strongly

Figure 28. Taxonomy of production instructions

department-oriented view is supplanted by a supra-departmental one; a country-specific view by an increasingly international and global one; and a focus on the individual industry or sector is supplanted by a view that takes in many industries.

The increasing importance of effective product development management, for example, makes clear the need for a supra-departmental view. In order to avoid costs for dead-end development and delays in development, concrete requirement profiles should be derived from consumer needs at an early stage, the existence of competing products should be investigated, and the requirements of downstream processing industries should be taken into consideration (see also Section 11.3 and Figs. 397 ff.). This information should be derived with internal development capabilities. Corporate management should be able to examine the development process at any time. Product quality and environmental protection are other examples where new information aggregates, cutting across classical departmental lines and extending all the way up to the corporate management level, are gaining in importance and must therefore be made available (see also Fig. 6. in [217]).

Any company that wants to make intelligent decisions on a worldwide basis regarding, for example, research and production sites and markets to be entered, while optimizing its decisions in a supra-departmental fashion, must have consistent, up-to-date information covering all countries of interest. The result will be increased demands on internal accounting in the sense of comprehensive control, that is, a control instrument for corporate management. Highly diverse, historically evolved structures cannot meet these requirements.

Particularly in the chemical industry, the product orientation that comes about because of manufacturing conditions must be harmonized with the interests of the consumer market, which often have to do with more than one product. An integrated way of looking at problems can result in synergistic effects in purchasing management

Figure 29. Level model of a corporation [168]

as well. A high degree of information transparency at a level higher than the industry or sector is therefore required.

The contribution of information technology at the corporate management level was very limited in the past, because it was restricted to supporting activities directly related to performance or order filling. The technology was marked by an orientation toward single tasks. Data structures were devised in a task-specific manner, in the narrowest sense; data bases were hierarchically structured (see also [144]). Data communications between programs also featured a mainly hierarchical structure. The task-oriented application systems based on this technology naturally could make little contribution to supra-departmental views. The core requirements of integration and flexibility could not be met. Personal computers were often made available to staff personnel on the management floors in an attempt to close this gap; most such computers were manually supplied with data from the functional systems and–not surprisingly–produced a wealth of incompatible data.

More recently, however, information technology has reached a stage in which the logical requirements of integration and flexibility can increasingly be realized. This applies both to information storage and to information retrieval and interpretation. The first comprehensive concept was developed for all engineering divisions of Bayer in 1989 – 1992 [178, 218].

Requirements imposed on the lower levels are illustrated for the case of production in what follows. A supra-departmental view is selected; that is, the interfaces to other departments are examined (see also Chapter 8).

Production Management Level. The discussion concerning the "factory of the future" has provided an outline of how the industrial production of the future will look. Although each expert's picture of this factory is different in detail, there is a consensus as to the need for increasingly extensive automation (see Fig. 124)

of production processes for reasons of quality assurance and optimal utilization of raw materials [216, 219].

Mass production is no longer a prerequisite for automation. The contemplated decentralized automation world, with the self-contained manufacturing islands already in existence, can be realized only if it is connected by unified information and communications systems. The objectives are to improve material flow, shorten storage times, increase the speed of transportation, and cut setup times when the product mix changes. These objectives are essentially the same no matter whether production is a manufacturing or a chemical process. Even so, there is a great difference between the implementations of these two types of systems.

Typical for the manufacturing industry are situations in which one or a few end products are assembled from many individual parts. The assembly process is complicated but lends itself to a virtually complete computer analysis [220].

In process industries, such as the chemical industry, the situation is reversed: There is one starting material from which one product or several related products are made (see diagram F8 on p. 379 in [216]). This simple, branching flowsheet allows stage-to-stage planning; any change will affect the next stage downstream, but can still be made at any time. The reason is that the process and product properties in each process element are interrelated (see Fig. 34). The interrelations, in general, can be described only in a phenomenological way, so that theoretical relations cannot be applied directly.

However, there are also many multiply branched flowsheets in which many end products are produced via several intermediates. These multi-stage batch or continuous production processes have the feature that the central event, the chemical reaction itself, is essentially a probabilistic occurrence and thus calculable only to a limited extent [220]. Such processes cannot be handled by production planning methods that are oriented toward parts lists.

Thus the systems integrated in CIM cannot be immediately and directly extended to continuous-process production.

The general structure shown in Figure 17 is now implemented in a manner specific to the production management level in Figure 30 [221, 222]. Production specifications supplied by the corporate management level are the following:

- Type of product
- Quantity of product
- Delivery schedule
- Special contract information (e.g., special packaging or formulation)

Detailing procedures are carried out with the aid of level-specific algorithms. Such procedures include adoption of production specifications, selection of basic recipes, comparison of material and apparatus requirements with inventories and free capacities, allotment to production units, assignment of apparatus-specific control recipes, and preparation of schedules. This detailing is often an iterative process that becomes necessary when the nominal/actual comparison in the evaluation algorithm signals disturbances in the production process or when preconditions for detailing are changed during the detailing process itself.

This block of functions has a strongly dispositive character. Once the detailing and disposition process has been completed, the production control function communicates it to the lower process control level in the form of a control recipe (when, what, where, how). The process control level in turn reports the relevant process and product data upward for further compression, either while the process is running or after it has been completed.

These downwardly and upwardly oriented algorithms include specific level data, which take the form of static inventories of apparatus and recipes. The updated execution plans, inventories, and actual product and process data are kept accessible in dynamic data bases.

This type of data management naturally includes a suitable documentation function, which can generate both routine reports and notices of special requirements. Another algorithm, not shown in Figure 30, deals with the optimization function. Points such as batch size, tooling time, startup and shutdown procedures, and stockpiles should be optimized. It is also important to modify the basic recipe and control recipe after the interpretation of process and product data (see Section 3.2) if product consequences reveal incompatibilities or if certain operating points turn out to be sensitive.

Figure 30. Production management level: structure and relationships

In the near future, such a production management system will become a permanent component of all production operations in the process industries. These functions will be implemented in a decentralized manner in individual operations.

Production management systems must be available in a configurable, off-the-shelf form, if only for economic reasons. The individual functions must therefore be implemented in the form of self-contained, comprehensible subsystems (Fig. 31).

According to Riemer, users can do the following on the basis of information that is kept accessible and up-to-date [223] (see also [221, 222]):

- On the basis of sales and operating quantity plans and using inventories and orders, they can determine in advance the net demand for products and feedstocks over all production stages (production planning).
- For this planned demand, on the basis of the instantaneous inventory, purchasing, and orderbook situation, they can ensure the timely procurement of all materials needed for fulfillment of the plan and monitor execution (demand disposition).
- They can keep their own production operations on target as to schedule, quantity, quality, and cost; allot materials and capacities; prepare working documents; continuously monitor production progress; and take prompt action when actual values deviate from nominal values (production control).
- They can accept specifications for production process control; support and monitor the process; and, by direct intervention as well as aggregation and structuring, prepare the continuously acquired production data for production control (process control; see Section 4.5).

Figure 31. Functions of a production management system [223]

- They can better support the management of object (products, packaging, etc.) inventories (inventory keeping).
- They can automatically or manually check and plan inventories on the basis of customer, internal, and production orders (inventory disposition).
- They can have the materials at their disposal stored, removed from storage, commissioned, packaged, sealed, and prepared for shipping (warehouse management).
- They can store materials and remove them automatically and with optimal routing of warehouse vehicles (warehouse control).
- They can monitor what is happening in the process, using the minimum number of clear signals and standard information, whether by ad hoc queries on the screen or as printout or graphical output (information and report management).
- They can acquire current data with the required level of detail, store the data, and make them available at various locations for the various functional divisions (corporate planning, controlling, accounting, procurement, duties and taxes, etc.) whether for information or for processing (interfaces).

The example of the production management level shows how the analog of CIM in manufacturing operations is computer integrated processing (CIP) [224] in continuous-process operations. Clearly, information has now become a factor of production.

Process Control Level. In the process control level, production orders (i.e., requirements on product, quantity, and delivery time) are transformed to realization processes. This change requires that a processing facility be available, the control recipe (i.e., the recipe adapted to the actual facility being used) has been determined, and all necessary resources are available (see Section 4.5).

The production process is generally subdivided into a sequence of process elements each self-contained in time. The structure of the process monitoring and control system must correspond to this horizontal breakdown of the process. Process control functions for plant sections must be performed in decentralized process control stations and must be suited to handling the information flow in parallel with the process [168, 225]. The performance of the production order then involves the allotment of partial control recipes to plant sections and the phase-byphase execution of the recipes through the basic functions of process control engineering (see Figs. 25 and 38).

Corresponding to the hierarchy of processes and subprocesses, the following functional complexes can be distinguished on the process control level (Fig. 32; see also Chaps. 7 and 8) [226]:

- Central functions for controlling the process itself (process operating computers, process control computers, process AI computers) and for controlling the process monitoring and control system (process engineering computers for design and diagnostic service). The complex operations involved in diagnosing possible error states of a process control system are merely indicated here (see Chap. 7 and Sections 11.2 and 11.3). The analogy with medical diagnostics should also be mentioned [227].
- Individual functions and coordinaton functions: the grouping of all process-level functions in aplant section(process section or process element) in a decentralized process control station (process-level components, PLC).
- System communications functions thought of as interface functions (system bus, field bus).

Phase Model of Production. An important aid for systems analysis of production processes is the phase model of production, which was adopted from software engineering [228] and belongs to the category of product nets. Other models lack any representation of product properties in between process elements, which is a prerequisite for constructable quality assurance and process reliability; the phase model supplies this representation. As suggested by Büsing [229], the phase model is readily derived from the basic flowsheet by attaching a label for the products between the individual process elements (Fig. 33). Each rectangular box stands for a process element, and each circle for a product. The individual process elements can be regarded as operators that transform the product properties (see "Transformation Principle" in Section 2.2). This method facilitates, among other things, the representation of information flows, which are needed to control the entire process in such a way that it is always held in its instantaneous nominal state. The method also requires a clear picture of what information is (or should be) available in and downstream of each individual process element for process monitoring and quality assurance (see Section 11.3 and [230, 231]).

Monitoring and control functions relating to certain product and/or process properties must be carried out in each process element. Product and process properties are the object classes of information about the process [232]. In Figure 34 product and process properties are listed for the example of one portion of a phase model. Every product or process property consists of a category and a value.

Special attention should be paid to scaling (see Section 3.1, Fig. 40, and [233]).

Process properties are the following:

- State variables such as pressure, temperature, and concentration. The process can be described in terms of these or with derived state functions.
- Process parameters such as heat-transfer coefficient and catalyst activity. These identify the constraints under which the process runs. Process parameters are stationary or at least quasi-stationary quantities.

Figure 32. Ideal structure of a process/production control system

– Control variables. These characterize intervention in the process.

In theory, the information budget of an entire process can be completely described with an appropriate set of these quantities. In practice, however, it often happens that not all the desired state variables and control variables can be measured or specified. Other information is often employed as a substitute:

– Setpoints are correlated with the desired control variables.
– Process indicators are empirically correlated with one or more state variables (these may also be, for example, product properties).

Product properties are the following:

– Physical quantities
– Chemical quantities
– Technological properties
– Product indicators

The last two items, again, are stand-in values. Technological properties are determined in special tests when relevant product properties depend on physical quantities that are difficult to measure or when the relationship to physical quantities is not known. Product indicators are correlated with physical or chemical quantities. Process properties can be employed as product indicators. The importance of this interplay between product properties and process properties was pointed out as early as 1967 when Rumpf introduced the concept of "property functions" [234].

Process indicators [235] and product indicators are the forerunners of the results that are now obtained by model-aided measurement techniques [236].

Product properties and process properties can be represented as property profiles information stream accompanying the material stream in the phase-model [168] (see Fig. 35). As nominal values, they are an essential part of the production instructions (Section 4.5). As actual values, they are used in process monitoring (Section 11.2), process control (Section 4.5), process analysis (Sections 3.2 and 11.3), and quality assurance (see also [216,237,238]). Note that it

Figure 33. Development of the phase model from the basic flowsheet

Figure 34. Excerpt of the phase model with product and process properties

is not just the values of the product properties that change from stage to stage; categories may also disappear and other new ones may appear. An understanding of this point is necessary in order to follow, for example, the suggestion of GILLES that quality be introduced as a state variable [230].

Figure 36 shows the property profile "quality" for an intermediate product, with its ranges of validity [239]. Figure 37 uses the same method to illustrate reliability.

Process engineering is customarily concerned with the material flow (and the energy flow, although this is not illustrated here) in a production operation, whereas the task of process control engineering is to deal with the information flow. The cross-link between the material flow and the information flow is provided by sensors and actuators. Sensor technology (Chap. 5) acquires the information required for process monitoring and control. The function of actuator technology is to derive actions on the process from information extracted from the information stream (see Chap. 6).

A phase model can be hierarchically refined in accordance with structuring principles. This

Figure 35. Profiles for process and product properties [135]

Figure 36. Material and information flows in the phase model of quality [238]

has been done for the example of automating a wastewater treatment plant [240]. Figure 38 shows the detailing process for chlor-alkali electrolysis [209].

Once the process analysis has been refined to the point that products cannot be broken down any further, a transition should be made from a product net to a causal model, either time-based or condition-based.

This transition is accomplished by transforming the interpretation "product with property profile" to the logical proposition, "product present in sufficient quantity and adequate quality at time t_0."

Figure 37. Material and information flows in the phase model of safety [238]

Figure 38. Detailing of the phase model for the example of chlor-alkali electrolysis

This logical proposition can be supplemented by further ones, for example:

- All resources needed for carrying out the process (plants, production specifications, monitoring and control system) are available and serviceable at time t_0
- All required energy sources are available in the proper quantity and quality at time t_0
- All safety devices are operable at time t_0
- Approval for startup has been issued at time t_0

With such a system of conditions applying to each minimal production unit, the way from product net to causal net is evident. In Figure 39, the transition is illustrated, starting with the phase model and ending with Petri nets, which in turn make it possible to present a control process in function charts complying with DIN 40 719 [241].

The left-hand part of Figure 39 shows the phase model of a simple production process. Each box represents a process element and corresponds to a unit operation. On this level of the hierarchy, changes in product properties are in the foreground; the way in which the unit operations are implemented is not of interest yet. If the top-down design process is continued and the technical implementations of the unit operations are specified (e.g., as shown in the diagram of Fig. 25), the middle part of Figure 39 shows the resulting detailed description. Each unit operation is now represented by its own Petri net relating to the setting of process properties. Basic functions are employed to establish the process properties. The production specification (or recipe) sets forth under what conditions which process property must be set to what value. Basic function elements are utilized in order to execute the basic functions. The resulting function chart describes the detailed solution in process control engineering terms (see also Section 4.5).

The phase model of production is thus the appropriate tool for describing (Chapter 10) and analyzing (Section 11.3) production processes with regard to quality assurance (Figs. 34, 35, 36), process reliability requirements (Fig. 37), static structuring (Fig. 38), and dynamic structuring (Fig. 39).

3. Knowledge about the Process

3.1. Principles

An essential feature of modern process control engineering is that knowledge about the production process is utilized to the fullest. "Knowledge about the process" does not refer just to knowledge of the static and dynamic attributes or properties of the object classes of the production process (e.g., process or product properties [242]), as now represented in entity–relationship models (Chap. 2) and often taking the form of observations and measurements. Instead, this phrase denotes knowledge about how these attributes depend on one another. Because they pertain to the system "production process," they will also be called "system quantities" in what follows.

This knowledge about the interdependence of system quantities can exist in various forms (e.g., characteristic curves, correspondence tables, mathematical process models). The power of such records depends heavily on the type of system quantity.

The type of quantity is established by the kind of scale used to measure it [243]. There are four types of scales: nominal, ordinal, interval, and proportional (Fig. 40). They differ in information content and interpretability. For example, the nominal scale permits only the relationship like/unlike (or equal/unequal) between two fixed values of a quantity; this applies to quantities such as tank numbers, production line numbers, and so forth. The ordinal scale contains the further information that an order relation exists, as in sensory evaluations or quality levels. With these scales, items can be identified not only by a wide variety of possible symbols but also by numbers, but the intervals between such numbers have no empirical meaning: The scales represent only topological information. Metric scales, where the differences between numerical values are interpretable, are the domain of physical quantities. An example is temperature measured in degrees Celsius, which is an interval scale. If the ratios between the numerical values of a quantity have a physical meaning, as is the case for masses, absolute temperatures, and so forth, the scale is said to be a proportional or ratio scale.

Figure 39. Transformation from the phase model via Petri nets to the function chart

Scale type	Interpretable relations				Examples
	Like/unlike	Ordering	Difference	Ratio	
Nominal	X				Tank no. Production no.
Ordinal	X	X			Quality classes Sensory evaluations
Interval	X	X	X		Temperature (°C) Time (h)
Proportional	X	X	X	X	Temperature (K) mass, energy

Figure 40. Types of scales

It is evident that the ways of representing knowledge depend on the type of scale applicable to the system quantities. Mathematical process models expressed in systems of differential equations can be employed only when the quantities lend themselves to a metric type of scale.

Before dealing with ordering methods for system quantities and the structure of mathematical process models, first some key concepts of systems theory will be elucidated that are significant in a process control engineering (PCE) context. The notion of "system" presented here contains a deliberate balance between needed generality (to afford sufficient degrees of freedom for separating the overall system into subsystems) and certain properties that are absolutely necessary for arriving at a general system structure. This is a point of great importance in the writing and application of software based on modular principles. The system concept is closely related to the phase model of production processes (Fig. 41) [244, 245], in which each process step can be interpreted as a transformation (see Sections 2.2 and 2.3). Certain product properties that exist before the inlet to the process stage, often represented as an unordered set $\{E_i\}_n$ or as the endpoint of a property vector in product space [246], are mapped onto the property vector existing after the process operation n with coordinates $\{E_\mathrm{i}\}_{n+1}$.

In simplified form, property vectors are written as x_in (inlet to the process stage) and x_out (outlet from the stage), as shown in Figure 41.

Figure 41. Phase model of a production process (excerpt)

The transformation can then be written as:

$$x_{\text{out}} = f\,(x_{\text{in}}) \tag{3.1.0}$$

In recent decades, the specialist literature has included many contributions attempting to justify a general theory of systems [247–254]. The axiom-based treatments, like all axiomatizations, represent a formal abstraction of concrete experience. The basic systems-theoretical concepts will be discussed here only in so far as they are essential in a PCE context.

In what follows, all system quantities are assumed to be "measurable," that is, representable on metrical scales.

The extension of this analysis to topological scaling, which has its own descriptive forms, leads to indefinite, conditional statements closely related to "fuzzy logic" and the methods of artificial intelligence (AI). They are not within the scope of this article (see also [255]). The scaling must, however, always be considered in the synthesis and analysis of production processes.

If the behavior of a reactor, such as a cascade of stirred tanks, a tubular reactor, or the like, is examined the system quantities can be classified in several categories.

For example, the following classes can be distinguished:

Inputs u_i: Mass flow rate in, concentrations and temperature in the inlet stream, cooling/heating temperature, etc.

Outputs y_i: Mass flow rate out, concentrations and temperature in the outlet stream, density of the outlet stream, etc.

System parameters p_i: Heat-transfer areas, heat-transfer coefficients, specific heats, enthalpies of reaction, kinetic constants, geometric quantities (pipe diameters and lengths), etc.

In this classification, the inputs play the role of independent (environmental) variables acting on the system. They can be thought of as perturbations or, when purposely manipulated, as control variables.

Figure 42. Schematic of a system

The outputs, on the other hand, are the means by which (at least in principle) the system acts on its environment (see Fig. 42).

It may seem surprising that state variables have not been mentioned up to this point. In fact, there is an important class of systems in which only steady-state processes take place, and in principle these can be described without the use of state variables. For example, in a cascade of stirred tanks operating in the steady state, the outputs are uniquely determined by the inputs. The introduction of state variables x_i is necessary only when investigating the time variations of systems. If, for example, the startup behavior of a reactor is to be studied it is not sufficient to know the time dependence $u\,(t\,)$ of the inputs; the "internal state" of the system must be known at least at a certain "initial time" t_0 before the outputs $y\,(t\,)$ can be predicted. This situation is reflected in the precise mathematical description when the system is formulated as a system of differential equations

$$\dot{x} = f\,(x, u, t) \tag{3.1.1}$$

which can be solved uniquely only by specifying an initial state x_0 at an initial time t_0.

Formulation (3.1.1) suggests that we generally attempt to describe a system by finding a vector x that has a minimum number of components. In the description of a chemical reactor, for example, one often arrives at a state vector x having the "reaction coordinates" ξ_i and the temperature T as components. All other quantities, such as concentrations, density, etc., are grouped in a vector z and can be stated as functions of x, u, and time t:

$$z = g\,(x, u, t) \tag{3.1.2}$$

The output vector y can be defined in a similar way:

$$y = C\,(x, u, t) \tag{3.1.3}$$

If a state vector x with the minimum number n of components is selected, n is said to be the number of degrees of freedom, or the order of the system.

Systems with finite order are also referred to as having lumped (concentrated) parameters. Systems with infinite order are then said to have distributed state variables. The state variables in such systems are generally continuous functions of the position coordinates.

The terms "system" and "process" are frequently used as synonyms. Here, however, "process" is defined as a one-parameter family of system states with the time t as the parameter. Accordingly, processes are generally dynamic; that is, their states are truly time-dependent unless special precautions are taken. Even when the inputs of a system are held constant over time, the system state will be a function of time at least during a startup phase. A special case of extraordinary importance for many problems in practical process control is that of stationary processes, where the system states $x(t)$ persist in a fixed state x_s and thus become independent of time. The state x_s is also said to be steady or stationary. The maintenance of specified steady states is one of the key tasks of process control. Steady states x_s should be considered only in time-invariant systems, where the time does not appear explicitly on the right-hand side of system equations (3.1.1) to (3.1.3). Clearly, the steady states in systems of this kind depend on the (constant) inlet variables u selected, and since $\dot{x}_s = 0$, the stationary system relating to (3.1.1) – (3.1.3) is immediately obtained if (3.1.1) is replaced by

$$0 = f(x_s, u) \tag{3.1.4}$$

For practical purposes, it is important to have a knowledge of the system stability near a stationary state x_s: If a process trajectory begins near state x_s, does the trajectory move farther away from x_s or return to x_s? This raises the question of how the system reacts to small disturbances away from its stationary point x_s. In order to handle this as well as some other questions, it is useful to have a concept of distance in relation to vectors. As is customary, the vector norm $\| x \|$ is used here; the distance between two vectors x_1 and x_2 is taken to be the norm of the difference: $\| x_1 - x_2 \|$. In what follows, the commonly encountered Euclidean norm

$$\|x\| = \|x\|_2 = \left(\sum_{i=1}^{n} |\xi_i|^2 \right)^{1/2} \tag{3.1.5}$$

is used, where the ξ_i $(i = 1, 2, \ldots, n)$ are the components of the vector x.

Reconsidering the stability in the vicinity of a stationary state x_s. We first recognize that only the state equations $\dot{x} = f(x, u)$ have any role to play in this respect. LYAPUNOV defines the stability of a stationary solution x_s of $\dot{x} = f(x, u)$ in the following way:

1) x_s is stable if, for any sphere K_r with arbitrary radius r about x_s, there exists a number $\varrho > 0$ such that the following statement holds for a process trajectory with initial value $x(t_0)$: $x(t)$ lies in K_r for all $t \geq t_0$ provided that $\| x(t_0) - x_s \| < \varrho$ (Fig. 43).
2) x_s is asymptotically stable if x_s is stable and there exists a number ϱ_0 such that $\| x(t_0) - x_s \| < \varrho_0$ implies the convergence of $x(t)$ to x_s; that is, $\| x(t) - x_s \| \to 0$ as $t \to \infty$.
3) x_s is said to be unstable if x_s is not stable.

Figure 43. Lyapunov stability

More on stability and related problems can be found in [256–258].

The property of asymptotic stability says nothing about the rate at which process trajectories beginning near x_s converge to x_s. The notion of the relaxation time T_R serves this purpose: If the estimate

$$\|x(t) - x_s\| \leq \gamma e^{-\frac{t - t_0}{T_R}} \tag{3.1.6}$$

holds for all trajectories beginning sufficiently close to x_s, then x_s is exponentially asymptotically stable with relaxation time T_R.

Systems with a globally valid relaxation time T_R (i.e., T_R independent of specially chosen inputs u) have a remarkable property:

For sufficiently slow variations in the inputs u, they behave in a quasi-stationary manner. More precisely: If the rate of change with time $\dot{u}(t)$ of the input vector satisfies $T_R \cdot \| \dot{u}(t) \| \ll \| u(t) \|$, the time-variant state $x(t)$ can generally be calculated from the formally stationary equation $0 = f(x(t), u(t))$. The quasi-stationary system is purely algebraic (it no longer contains differential equations), and its dynamics depend solely on the time dependence of the inputs $u(t)$. The system thus has no intrinsic dynamics but responds to the time variations of u without inertia (time lag).

The transition to a quasi-stationary system is a radical reduction of the system: The initial system (3.1.1) has n degrees of freedom, but the new system has no internal degrees of freedom. Consider, for example, an ideally mixed stirred tank containing an indicator substance whose time-dependent concentration $u(t)$ in the inlet fulfils $\tau \cdot | \dot{u}(t) | \ll | u(t) |$ (where τ is the mean residence time in the tank). The outlet concentration $y(t)$ then satisfies $y(t) = u(t)$. The intrinsic dynamics of the tank, represented, for example, by its residence-time spectrum, is no longer identifiable.

The quasi-stationary property of subsystems within a specified overall system is not just important for numerical treatment: It is one of the key concepts for explaining "synergetic" effects in nonlinear systems [259].

Finally, two terms whose understanding is basic to the mathematical solution of most control engineering problems: controllability and observability [254, 260–264].

If at time t_0 a system is in a certain state x_0 and the inputs exhibit a time dependence $u(t)$ such that the system is in a specified state x_1 at a later time t_1, the system is said to be controllable from x_0 to x_1. If any x_0 is controllable to any x_1, the system is said to be completely controllable. Consider, for example, a stirred reactor in which the reaction $A \rightarrow B$ takes place, whereby the reaction is dependent on the temperature Θ. Let the state vector be $x = (\Theta, [A], [B])^T$, and the inputs u_1 = heating/cooling temperature Θ_K and u_2 = inlet concentration $[A]_{in}$ of species A. Then any state x_0 is controllable to any state x_1 provided the time interval from t_0 to t_1 is sufficiently long. However, if u_2 is not permitted as an input, then clearly x_0 is not controllable to x_1 if $[A]_0$ and $[A]_{in}$ are smaller than $[A]_1$. The controllability concept is of crucial importance for the problem of feedback control (returning the state to the setpoints) and the related problem of pole specification.

In the same way that the controllability links inputs u with state variables x, the observability relates the outputs y to the state variables. The state x is said to be observable at time t_1 if $x(t_1)$ can be determined from a knowledge of $y(t)$ in the finite time interval $t_0 < t < t_1$. In the reaction system discussed above, for example, suppose the state variable Θ is simultaneously taken as a measured quantity y. Then the remaining state variables [A] and [B] can be calculated from the time variation of the temperature Θ, and are hence observable, provided the enthalpy of reaction is nonzero. The observability concept is basic to the concept of the Luenberger observer in control engineering [254, 260, 265, 266].

3.2. Analysis Methods for Process Quantities

Introduction. Suppose k process quantities (i.e., state variables, inputs, or outputs) are measured at a certain time. These observations can be expressed as a k-dimensional vector $V(1, \ldots, k)$. If there are many observations, they form a cluster of points in a k-dimensional vector space, which will be called observation space or property space in what follows. Mathematical methods of linear algebra and statistics now become applicable [246]. Important uses of these methods include data reduction and transformation. A data reduction can be performed if the point cluster lies, at last approximately, in an m-dimensional subspace of the k-space. A transformation changes the coordinate system; that is, it generates a more easily handled representation by replacing the measured process quantities with "parameters" calculated from them.

Statistical models are valid only in the region studied; extrapolation beyond this region is not permitted. Furthermore, such models hold only under the assumption that all independent variables influencing the dependent variables have been identified.

Preparation of Process Properties. A statistical analysis can be broken down into the functions of acquisition, archiving, preparation,

Figure 44. Acquisition, archiving, preparation, and interpretation of product and process data

and interpretation (Fig. 44). Statistics proper is part of the interpretation function and will be discussed in depth in the next section. Acquisition and preparation, however, are vital for the practical use of statistical methods and should therefore be explained in further detail.

Acquisition. Statistical research often entails a laborious data collection process. In plants equipped with process monitoring and control systems, the system acquires a large amount of process data for observation and for use in plant operation. Thus it is obviously desirable to use process monitoring and control systems to acquire data for use in statistical studies. When this is done, archiving must be added to the functions of a typical system so that data collected at a given time can be accessed at a later time. What is more, certain data on the configuration of the process control system must also be archived so that the archived process data can be properly interpreted even after a reconfiguration. Statistical software packages (e.g., SAS) can be used for the actual interpretation step; such packages for use on PCs offer good functionality at reasonable prices.

Preparation (Formatting). The starting point for many statistical procedures is a matrix W in which the rows represent observations and the columns represent the observed features (Fig. 45).

A typical requirement for a process monitoring and control system is that k process quantities be selected in a specified time interval from t_0 to t_m at a specified sampling rate. This would yield an $m \times k$ matrix (i.e., a matrix having m rows and k columns), which can be input directly to statistical analysis.

However, commercial software for process control systems does not to have this functionality. Nor does the simple selection of an $m \times k$ matrix satisfy all practical requirements, since professional presentation requires that descriptive data (name of measurement point, unit of measurement, etc.) be included. The extracted data must be output in a format that can be interpreted by commercial PC software. Because the result of data preparation is essentially a matrix, it makes sense to adopt a file format used in spreadsheet-type analysis.

Software. The preparation (formatting) and statistical analysis of process properties is not a

Figure 45. Data matrix for observations

routine activity for the person who does it. This makes it all the more important for the software to have a simple user interface. The format of the measurement station list must offer an easy way of marking the stations chosen for data acquisition (Fig. 46) [267]. Since all the selected points are sampled at the same time intervals, which as a rule do not coincide with the rhythm of data acquisition, an interpolation type must be specified for each individual station. The interpolation types include linear interpolation; constant incrementing of the measured value up to the next measurement; and mean, minimum, or maximum value (when several acquisition events fall into one data-preparation interval).

Once the process information has been prepared, the data can be transferred to a statistical software package via a suitable interface. As already mentioned, the user expects that not only the measurements, but also the descriptive data, will be extracted from the process control system. The statistical package must then use these descriptive data as captions, axis labels, etc., without any intervention by the user.

Many applications allow the user to define a catalog of statistical methods that can be employed. In such cases, a user interface with the following properties can then be implemented, either as part of the statistical software package or as an add-in:

- Spontaneous selection of a variable as a dependent variable
- Selection of statistical methods by marking a list
- The possibility of depositing rules for conditioned or excluded statistical methods
- Dynamic specification of numbers of variables and observations and identification of descriptive data for statistical procedure

If the statistical package employed does not have this functionality, the user interface can be implemented with additional software. A statis-

Figure 46. Interpolation of raw data to produce a standard table for subsequent analysis

tical procedure will then be written in which the numbers of variables and observations, names of dependent variables, and descriptive data are represented by placeholders. The steps in the procedure are defined as statistical methods. The add-on software uses selection rules to interpret user inputs, descriptive data, and files, replaces the placeholders, and ignores methods not selected. The procedure that results can now be handled directly by the statistical package.

Statistical Methods. This survey briefly describes individual statistical methods and discusses their applicability to the interpretation of process information.

Elementary Statistics. The examination of position parameters, such as mean, median, and mode, is meaningful especially when the process is expected to be stationary or pseudostationary (e.g., a constant flow rate in a continuous process). If the usual variability of the process has already been determined on the basis of large data sets, statistical quality control with control charts is possible. The purpose of control charts is to discriminate as accurately as possible between normal fluctuations of a value and unusual variations.

An important point when using a statistical test is to follow a definite methodology. This includes exact formulation of the hypothesis, so that the probabilities of Type I errors (rejection of a correct hypothesis) and Type II errors (acceptance of a false hypothesis) can be precisely studied and evaluated.

In many cases it is useful to determine whether a classical distribution function can be assumed. The important tests used in practice–the F test (comparison of two variances) and the t test (comparison of two means)–assume a normal distribution of the population.

Experimental Design. The concern of experimental design is to determine which of k potential factors $x_1, \ldots, x_k$ actually influence a dependent variable y, and to do so in the most efficient way by means of planned experiments. Two-level factorial experiments are important. First, a realistic minimum value (− level) and a realistic maximum value (+ level) are selected for each factor. Not only quantitative factors but also qualitative ones are possible; for example, + denotes product from plant A and − denotes product not from plant A.

The complete design then consists of 2^k experiments. It is obtained by taking all combina-

tions of the − and + levels for the w_i. The effects are the actions of the factors themselves, as well as the interactions of two or more factors. The level of an interaction is obtained by multiplying the levels of the individual factors. For example, if the factors w_1, w_2, w_3 in an experiment have levels +, −, −, then in this test the effect $w_{1,2,3}$ has level +.

After performing the experiments, the effects are calculated by taking the mean of all results from trials in which this effect had level + and subtracting the mean of all results from trials in which the effect was −. The literature gives formulas for deciding, on the basis of these results, whether an effect is significant.

If the assumption is justified that interactions of more than two factors are not to be expected, then the complete factorial experimental design can be replaced by a fractional factorial design calling for fewer tests.

Methods for generating partial factorial designs can be found in, for example, [268]. Software for creating and evaluating designs is available.

The interpretation of two-level factorial experimental designs is a special case of analysis of variance, a technique that can be used with any number of levels. The trick is to use two-level factors first to investigate which potential factors truly affect the experimental result y. The nature of this influence (e.g., whether it is linear) is investigated only after the merely notional factors have been identified and omitted.

Principal Components. On economic grounds, it is often not possible to carry out a designed experiment, and one must be content with random process measurements from the plant. It may be difficult to gain any knowledge from such a collection of data. Principal-component analysis is a method of orienting and, in some cases, reducing high-dimensional observations.

If the observations exist in k-dimensional space, principal-component analysis answers the following question: For any i, $0 < i < k$, how well can the k-dimensional observations be described in a subspace U of dimension i (Fig. 47) ? While a regression model minimizes only the squared distances in the direction of the dependent variable y, principal-component analysis minimizes the sum of the squared Euclidean distances between U and the individual observations. In this way, all the k process variables are equivalent; none is identified as dependent. Scaling now becomes a problem, especially when a variety of physical units are present. A change of scaling means a numerical change in the Euclidean distance in the k-dimensional observation space, and thus changes the result of the principal-component analysis. In practice, all the process variables are usually scaled so as to have mean 0 and variance 1. When this is done, however, the scaling becomes experiment-dependent. It is also possible to determine a technical minimum and maximum for each process variable, then define the scaling to give these the values −1 and +1.

Figure 47. Effect of the shape of a point cluster on the principal components

The principal-component analysis determines, for every i, $0 < i < k$, the i-dimensional subspace U_i for which the sum of the squared Euclidean distances to the observations is a minimum. The procedure has the convenient mathematical property that these subspaces are all nested, that is, $U_1 \subseteq U_2 \subseteq \ldots \subseteq U_{k-1}$. They can thus be stated as a sequence of k basis vectors; these are the principal components. The mathematical procedure yields an eigenvalue for each principal component; the sum of all the eigenvalues is k. If, for some i, the sum of the first i

eigenvalues $l_1 + l_2 + \ldots l_i$ is close to k, the point cluster of the observations can be regarded as i-dimensional to satisfactory accuracy. Often, $c_i = (l_1 + l_2 + \ldots + l_i)/k$ is used as a parameter, known as the variance contribution of the first i principal components; this has a maximum value of 1.

Time-Series Analysis. A typical problem leading to a statistical study of process variables is the estimation of dead times. The central concept is cross-correlation: The correlation coefficients between the time series $x(t)$ and all time series $y(t+nT)$ are calculated, where T is the sampling rate. If N denotes the value of n that has the largest correlation coefficient, then NT is the estimated dead time.

This method has been extensively developed. Nonlinear relations between $x(t)$ and $y(t)$ can now be included, and processes for which the dead time is not a constant but depends on the nature of $x(t)$ can be investigated.

Systems Engineering. A number of software packages for the statistical analysis and graphical presentation of data have become commercially established. The methods employed are complex and exist in a wide range of variations, and no practically useful functionality is left out. The publishers of most of this software offer their products for a variety of system platforms (MS-DOS, UNIX, etc.), and data can be shared with other widely used software products (database management programs, spreadsheets, etc.). Examples of established statistical packages are SAS and RS/1. These products are continually being upgraded as standards develop (e.g., X/Windows). While market conditions are generally good for statistical applications software, there are some problems having to do with inadequate management of process data (Fig. 48). In practice, statistical analysis includes the functions of data acquisition, archiving, and preparation; these have already been described. But no software standards have yet been adopted in this area, and there are no dominant products in the market. One step in the right direction is The Fix, a process data acquisition system published by Intellution for MS-DOS. The system supports the preparation of historical data in Data Interchange Format (DIF), which many spreadsheet programs, as well as the SAS and RS/1 statistics packages, can handle.

Process monitoring and control systems published by the established firms, however, do not support the generation of a matrix (Fig. 49) including descriptive headers in place of a series of measured values.

Figure 48. Problems in transferring inadequately organized data to statistical software

Figure 49. The data matrix as interface between process control or data acquisition system and statistical software

3.3. Process Models

Introduction. The general concept "model" is very broad. Any means of analysis and synthesis that is used in learning about reality or in actively designing and fabricating human artifacts can be called a model (see also Section 2.2). Typically, models are simplified pictures from a particular viewpoint of the properties and functions of the real object on which they are based. As for the chemical plant models in Figure 50 (see next page), it can be stated generally that a model reflects only a certain portion of the whole, from a certain aspect and for certain purposes.

The example clearly shows the three main features of all models [269]:

1) Mapping.
2) Abbreviation: The model generally lacks many of the attributes of the original. In fact,

this information loss is often an advantage because incidentals can be ignored in creating the model. One discards intellectual ballast so as to be able to focus better on the interesting aspect of the whole. These comments are closely related to the third model characteristic.

3) Pragmatism: The model represents the original, aiding in the acquisition of knowledge and permitting a limited range of mental or actual operations.

Figure 50. Model and reality

In contrast to models that represent physical images or simulations of particular originals, mathematical models are mental constructs that generally apply to an entire class of objects and situations. They thus fulfill a key prerequisite for being "scientific" ("Scientific theories are general laws" [270]). Mathematical models are formulated (as differential equations, etc.) in terms of variables that cannot enter into a concrete calculation until boundary or initial values and other model parameters have been established. It is in setting these values that the user applies the mathematical model to the "special case."

The mathematical model, as the image of an entire class of processes, constructed with the aid of the basic disciplines (chemistry, physics, process engineering, etc.), starts out with only a theoretical or prospective relationship to actual calculations (Fig. 51). Its use in computation depends on the existence of a solution algorithm; in general, a computer program is still needed. The usefulness of a mathematical model is thus determined not only by its consistency with the underlying real object, but also by the bounds set by numerical mathematics and computing capacity set. These limits are still relevant in practice today, because many of the processes found in the chemical industry are highly complicated from the standpoint of mathematical modeling (e.g., emulsion polymerization with its many associated phenomena). Advances in the calculability of mathematical models are essentially governed by advances in computer hardware. An example is the method of finite elements, used for the solution of partial differential equations. Although the fundamental idea was formulated by Courant in the 1940s [271], this publication remained largely unknown, and finite elements were "rediscovered" by engineers in the 1950s. Only then did rapid progress occur in its numerical principles, and these advances accompanied the development of computer technology.

Figure 51. From process to computed result

Another example is adaptive control. The first publications on this method appeared in

the 1950s [272, 273], but the impetus for further study came only when the development of fast process control computers made it practically feasible.

The creation of a mathematical model thus means keeping track of numerical problems, the capacity of the computers to be used, and (especially when writing large programs) software engineering considerations. In particular, the three main sources of error (modeling errors, procedural errors, and rounding errors) must be treated as a compromise to minimize the total error. This topic has also been dealt with in [274, 275].

Mathematical Models: Survey and Structural Properties. This section treats mathematical models that describe the space – time behavior of processes whose model variables and parameters are measured on at least an interval scale (see Section 3.1). The general mathematical description of such processes consists of coupled systems of partial differential equations. The models under consideration are those in which the system is described in terms of model variables classified as inputs u_i, state variables x_i, outputs y_i, and model parameters p_i (see Section 3.1).

In creating and using mathematical models of process apparatus, it is particularly important that the model nearly always consists of two parts, the physicochemical part and the apparatus-specific part (Fig. 52). The physicochemical component of the model includes relationships whose validity is totally independent of the particular apparatus in which the modeled operations take place. This self-consistency of the physical component insures that the model can be applied to a variety of apparatus; this feature is naturally a great advantage in the architecture of large applications software packages (material property databases, etc.). The fact that apparatus and facilities can be simulated with off-the-shelf engineering software, without regard to the wide range of variation in the details, is a consequence of the strong structural similarity of the essential apparatus-specific process equations. All space – time processes taking place in continuous-flow equipment, for example, obey balance equations written for conserved quantities (e.g., energy and chemical species), in which one side always contains terms known from the continuity equation while the other side contains diffusive terms, sources, and sinks, which represent only the pure, non-apparatus-specific physics. As special cases, the continuity terms contain both purely spatial variability (steady continuous process) and purely temporal variability (batch process).

1. Physicochemical part (state relations)

Enthalpy	$J = J(x, T)$
Density	$\varrho = \varrho(x, T)$
Ideal gas law	$pV = vRT$

2. Apparatus-specific part (process equations)

Balance equations $\frac{\delta x}{\delta T} + \mathrm{div}\,(\vec{v}\,x)$

= diffusion term + sources − sinks

"Engineering formulas"

Initial and boundary conditions

Figure 52. Structure of mathematical process models

"Stage models" are often used in simulation. Such models describe apparatus or parts of apparatus in terms of fictitious or real stages that have no spatial variability of the state quantities in a finite volume. The differential operator $\mathrm{div}\left(\vec{v}\cdot x\right)$ is then replaced by appropriate difference operators.

In addition to the balance equations, the typical information includes initial and boundary conditions for the apparatus-specific equations. A number of software products now available make extensive use of these structural properties, both in their design and in the user interface. The conserved quantities are momentum (Navier – Stokes equations), mass (continuity equation), and enthalpy (heat balance). Other conserved quantities, as well as sources and sinks, can generally be programmed by the user.

The divergence term $\mathrm{div}\left(\vec{v}\cdot x\right)$ has uses that go far beyond describing convection in space. The balance equation can be applied to other pseudospatial propagation phenomena without change.

Two examples:

1) Particle-size distribution
   "Space coordinate" = particle diameter
   Velocity v = rate of growth of particles
   Conserved quantity x = number of particles
2) Particle age distribution
   "Space coordinate" = particle age τ

Velocity $v = d\tau/dt = 1$
Conserved quantity x = number of particles

As a concrete example to show how the model equations are split, Figure 53 shows the mathematical model of a distillation column.

1. Physicochemical part (state relations)

Equilibrium relations	$y^* = y(x, T)$
Boiling curve	$p = p(x, T)$
Ideal gas law	$pV = vRT$
Liquid density	$\varrho = \varrho(x, T)$
Enthalpy of liquid	$J = J(x, T)$
Heats of vaporization	$r = r(T)$
Reaction rates	$R = R(c, T)$

2. Apparatus-specific part (process equations)

Material balances	$(n_i \cdot x_i) = \Sigma$ inputs $- \Sigma$ outputs
Heat balances	$W_i = \Sigma$ inputs $- \Sigma$ outputs
Separation effect of trays	$\dfrac{y_i - y_i + 1}{y_i^* - y_{i+1}} = E$
Pressure balance	$\Delta p_i = g_1$ (flow rates, densities, x, T, geometry)
Weir relation	Liquid flow rate = g_2 (liquid volume, geometry)

Figure 53. Mathematical model of distillation columns

For the physicochemical part, equilibrium relations are needed between the mole fractions in gas and liquid, the relation for the boiling point line (which interelates the pressure with the molar fraction of liquid and the temperature), the ideal gas law, and relations for the liquid density, liquid enthalpy, heat of vaporization, and (if appropriate) reaction rates. All these are purely physical state equations. Given this list of relationships, only an expert might suppose that someone is creating a mathematical model for a distillation column. The apparatus component of the model is required to reveal which apparatus is to be modeled. In the case of a distillation column, this would comprise the material and heat balances for condenser, trays, bottom, and vaporizer; the separating effect of the trays (giving the departure from ideal equilibrium, described by, for example, the Murphree efficiency E); the pressure balances for determining the pressure drop across individual trays (these use basic geometrical data such as perforation diameter, tray thickness, and active tray surface area); and finally a weir relation to give the downflowing liquid flow rate (again based on geometrical data such as weir height).

Spatial discretization with stage models is a special case of a widespread practice (e.g., difference methods, method of finite domains, Galerkin method, with the important special case of finite elements), which meets practical requirements because partial differential equations can generally be solved only by discretizing to finite-dimensional substitute models. These are represented as systems of differential algebraic equations (DAE systems) of the form

$$A(x, z, u)\,\dot{x} = f(x, z, u) \tag{3.3.1}$$
$$0 = g(x, z, u) \tag{3.3.2}$$

The output equation

$$y = C(x, u) \tag{3.3.3}$$

is also needed.

The special structure of the left-hand side of (3.3.1), where the matrix A depends on x, z, and u, expresses the fact that nearly all process models of practical relevance are linear in the time derivatives $\dot{x}$ *of the state variables* x. For the numerical solution of DAE systems, see [276, 277].

In Section 3.1, the state vector x with minimum number n of components was introduced to describe the system, where n is equal to the number of degres of freedom in the system. Unfortunately, the mathematical modeling of a system based directly on the physical phenomena often leads to DAE systems (3.3.1), (3.3.2) in which the number of degrees of freedom is smaller than the number of components of vector x (DAE systems with index greater than 1).

For example, in mathematical models of distillation columns, the boiling-line equation couples the pressure with the differential equation variables temperature and mole fractions. If the pressure is assumed to be constant, the number of degrees of freedom is thus reduced.

The numercial handling of such systems with index greater than 1 is problematical because the solution contains time derivatives of the inputs $u(t)$ up to order $q - 1$, where q is the index of the DAE system [278–280]. Thus DAE systems with index greater than 1 are mixed problems involving both integration and differentiation.

Example: The equation $\dot{x}_1 = x_0 - x_1$ (stirred tank with mean residence time $\tau = 1$) with $x_1 = u(t)$ [with $u(t)$ a specified function] has solution $x_0 = u(t) + \dot{u}(t)$. Here the number of degrees of freedom is actually zero; the index is 2.

Design problems such as this example, where certain state or initial values are specified and certain inputs are to be calculated, generally have a high index.

To transform a DAE system with index $q \geq 2$ to an equivalent $q = 1$ system, index reduction methods have been devised [278, 280]. For large models, however, these are often time consuming since the transformations must be performed with closed formulas, and an expert system that will let the computer do the transformations is not available.

If the system is discretized not only in space but also in time, by considering the system quantities only at specified (generally equally spaced) times $t_i = t_0 + i\Delta t$ $(i = 0, 1, 2, \ldots)$, the time-continuous models (3.3.1) – (3.3.3) become time-discrete models of the form

$$A(x_i, z_i, u_i)\, x_{i+1} = F(x_i, z_i, u_i) \tag{3.3.4}$$

$$0 = g(x_i, z_i, u_i) \tag{3.3.5}$$

$$y_i = C(x_i, u_i) \tag{3.3.6}$$

Time-discrete systems offer a number of advantages, including simpler numerical solution. Because of their inaccuracy (especially when the system behaves in a strongly nonlinear manner), their use is generally recommended only for on-line adaptation of the system parameters. The structural properties in most cases are invariant to the change from time-continuous to time-discrete models, but there are changes in, for example, the concepts of observability and controllability [260].

Up to now we have discussed dynamic models that include both spatial and temporal variations of the system. These models are naturally of interest as aids where the time dependence is an essential feature of the problem. These situations include studies of system behavior by means of:

1) Stability analysis
2) Step response of the system
3) Controller design and tuning of controller parameters; simulation of genuinely dynamic processes such as batch operations
4) Startup and shutdown strategies in continuous equipment
5) Failure analyses

Finally, dynamic models are increasingly used in identifying optimal process control (e.g., in time-optimized control of batch processes when safety and product quality are competing considerations). Besides these advanced simulation techniques, dynamic process models are used on-line in the form of observers, such as the Luenberger observer [265, 266] or the Kalman – Bucy filter [281, 282].

As discussed in Section 3.1, the notions of steady-state and quasi-steady-state process models come directly from Equations (3.3.1) – (3.3.3) if $\dot{x}$ is set equal to zero. Naturally, steady-state process models find use chiefly with steady continuous processes and in connection with problems such as

1) The design and optimization of plants and apparatus
2) The analysis of plant characteristics

The state variables can in principle be eliminated from these models, so that a direct relationship appears between the outputs y and the inputs u:

$$y = h(u) \tag{3.3.7}$$

Equation (3.3.7) is the simplest case of a transfer model, in which the value of the output vector y is obtained directly from that of the input vector u by means of a calculation specification. Such a simple link between y and u cannot in principle hold in dynamic process models.

For example, the transfer function between the concentrations u (input) and y (output) for an ideally mixed stirred tank with no reaction is given by

$$y(t) = \frac{1}{\theta} \int_{-\infty}^{t} \mathrm{e}^{-\frac{t-\tau}{\theta}} \cdot u(\tau)\, \mathrm{d}\tau \tag{3.3.8}$$

where θ is the mean residence time.

This formula represents the "steady-state" solution of the dynamic model

$$\dot{x} = \frac{1}{\theta}(u - x) \tag{3.3.9}$$

$$y = x \tag{3.3.10}$$

It is important, however, that in Equation (3.3.8) the value of y at time t does not, as in (3.3.7), depend solely on the value of the input u at time t, but on the time variation of u throughout the past.

Transfer models for dynamic systems are functionals of the form

$$y(t) = h_1\left(t, u(\tau)_{\tau \leq t}\right) + h_2(t, u(t)) \quad (3.3.11)$$

The second term $h_2(t, u(t))$ in Equation (3.3.11) takes into account the possibility that the effect on y of time variations in u may be present not just in smoothed form, as in h_1 (discontinuous functions in u become continuous functions y; continuous u become continuously differentiable y), but in unsmoothed form. Then h_2 describes the "feedthrough" of u to y.

The importance of transfer-function models (Eq. 3.3.7 and 3.3.11) is that they make it possible to examine how the inputs u affect the outputs y without knowing the internal structure of the system (represented by the state variables x_i and their dependences on u and on one another). This may be the only approach in, for example, complex systems (e.g., dynamics of drugs in human beings and animals) or in design calculations where only the input/output behavior of the apparatus is known at first and the detailed engineering has not yet been done (e.g., pre-simulations based on linear quantitative balances).

Transfer-function models thus belong to a class of models whose structure is only slightly or not at all influenced by the "nature" of the system being modeled. These purely mathematical (statistical or regression) models therefore offer great freedom in the choice of model structure. The model parameters must always be obtained by fitting to measurements made in the underlying real system. Because such regression models are based on measurements (see Section 3.2) and no attempt is made to derive a predictive theory from them, the model cannot be applied or extrapolated beyond the range of the measured values and the specific apparatus on which the measurements were performed, in contrast to theoretical models. While pure regression models cannot be employed in the design phase, they have an important application in on-line simulation (see Section 11.3). Measurements on the running process make it possible to treat and adjust the model parameters as time-variant quantities, so this accurate knowledge of the model parameters permits the use of regression models with simple structure. When these "adaptive" process models are used, the control parameters can also be modified on-line to fit the current process situation. This technique is called "adaptive control."

Particularly important here are linear process models. In the state – space representation, they have the form

$$\dot{x} = A(t) \cdot x + \mathrm{B}(t) \cdot u(t) \quad (3.3.12)$$

$$y = C(t) \cdot x + \mathrm{D}(t) \cdot u(t) \quad (3.3.13)$$

The system parameters are thus the totality of components in the matrices A (system matrix), B (input or control matrix), C (observation matrix), and D (pass-through matrix), which completely characterize the model of Equations (3.3.12) and (3.3.13). For this model, the block-diagram visualization customary in publications on control engineering takes the form shown in Figure 54.

Figure 54. Block diagram of a linear process model

The input x_0 to the integrator block symbolizes the effect of an initial condition $x(t_0) = x_0$ on the solution behavior. The transfer-function model associated with Equations (3.3.12) and (3.3.13) has the form

$$y(t) = \int_{-\infty}^{t} K(t,\tau) \cdot u(\tau)\, \mathrm{d}\tau + D(t) \cdot u(t) \quad (3.3.14)$$

where the matrix $K(t, \tau)$ depends on the time variables t and τ. Equation (3.3.14) gives a mapping $y = F(u)$ from the set of input functions u into the set of outputs y; this mapping satisfies the superposition principle

$$F(u_1 + u_2) = F(u_1) + F(u_2) \quad (3.3.15)$$

(image of sum = sum of images) and

$$F(\alpha \cdot \mathrm{u}) = \alpha \cdot F(u) \quad (3.3.16)$$

(image of α times $u = \alpha$ times image of u).

Linear Process Models. The linear process models introduced above require some more discussion, since they are still very important in both systems analysis and the design and on-line modeling of control systems (despite advances in the calculation of nonlinear systems). Their importance undoubtedly stems from the fact that their simple structure can be completely understood from fundamentals and that many structural properties of nonlinear process models are conserved in linearization (approximation of nonlinear models by linear ones).

What is more, the calculation of linear process models involves far fewer problems than that of nonlinear models. The use of linear models should always be considered when it is certain that the process trajectories in state space do not depart from the region in which linearization is valid. An example is control to maintain a stationary operating point by using an on-line linearized process model.

Special importance attaches to the time-invariant linear models

$$\dot{x} = A \cdot x + B \cdot u\,(t) \tag{3.3.17}$$

$$y = C \cdot x + D \cdot u\,(t) \tag{3.3.18}$$

which are set by the constant (time-invariant) matrices *A, B, C,* and *D*.

As an example of linearization about a stationary operating point, let us analyze the reaction A → B taking place in a stirred tank, using the heat balance. The nonlinear process model is described by the equations

$$\dot{a} = \frac{1}{\theta} \cdot a_{\mathrm{E}} - \frac{1}{\theta} \cdot a - S \cdot e^{-T_{\mathrm{A}}/T} \cdot a \tag{3.3.19}$$

$$\dot{T} = \alpha\,(T_{\mathrm{c}} - T) + \beta \cdot S \cdot e^{-T_{\mathrm{n}}/T} \cdot a + \gamma \cdot (T_{\mathrm{E}} - T) \tag{3.3.20}$$

where a and a_{E} are the concentrations of A in the tank and in the inlet stream; T is the reaction temperature, T_{E} the inlet temperature, and T_{C} the coolant temperature; θ is the mean residence time and S the collision factor; T_{A} is the activation temperature of the reaction; and α, β, and γ are further model parameters.

Consider given values of the inputs $\bar{a}_E$, $\bar{T}_{\mathrm{E}}$, and $\bar{T}_{\mathrm{K}}$, and the associated stationary values $\bar{a}$ *and* $\bar{T}$ of the state variable. If the deviations are defined as $a = \bar{a} + x_1$, $T = \bar{T} + x_2$, $a_{\mathrm{E}} = \bar{a}_E + u_1$, $\bar{T}_{\mathrm{E}} = T_{\mathrm{E}} + u_2$, and $T_{\mathrm{K}} = \bar{T}_{\mathrm{K}} + u_3$. Linearization then yields the relations

$$\dot{x}_1 = \frac{1}{\theta} u_1 - \frac{1}{\theta} x_1 - S \cdot \mathrm{e}^{-T_{\mathrm{A}}/T} \cdot x_1 - \frac{S \cdot T_{\mathrm{A}}}{\bar{T}^2} \mathrm{e}^{-T_{\mathrm{A}}/\bar{T}} \cdot \bar{a} \cdot x_2 \tag{3.3.21}$$

$$\dot{x}_2 = \alpha \cdot u_3 - \alpha \cdot x_2 + \beta \cdot S \cdot \mathrm{e}^{-T_{\mathrm{A}}/\bar{T}} \cdot x_1 + \frac{\beta \cdot S \cdot T_{\mathrm{A}}}{\bar{T}_2^2} \mathrm{e}^{-T_{\mathrm{A}}/\bar{T}} \cdot \bar{a} \cdot x_2 + \gamma \cdot u_2 - \gamma \cdot x_2 \tag{3.3.22}$$

If the temperature is known as an output (measurement) and we accordingly set $y = x_2$, the linearized system has the system matrix

$$A = \begin{bmatrix} -\frac{1}{\theta} - S \cdot \mathrm{e}^{-T_{\mathrm{A}}/\bar{T}} - \frac{S \cdot T_{\mathrm{A}}}{T^2} \mathrm{e}^{-T_{\mathrm{n}}/\bar{T}} \cdot \bar{a} \\ \beta S e^{-T_{\mathrm{A}}/\bar{T}} - \alpha - \gamma + \frac{\beta \cdot S \cdot T_{\mathrm{A}}}{T_2} \mathrm{e}^{-T_A/\bar{T}} \cdot \bar{a} \end{bmatrix} \tag{3.3.23}$$

the input matrix

$$B = \begin{bmatrix} \frac{1}{\theta} & 0 & 0 \\ 0 & \gamma & \alpha \end{bmatrix} \tag{3.3.24}$$

observation matrix $C = (0\ 1)$, and feed-through matrix $D = (0\ 0\ 0)$.

The stability (also of nonlinear systems) at a stationary state x_{s} can be investigated with the system matrix A obtained by linearization about this state. Thus, for example, the system is asymptotically stable at x_{s} if and only if all the eigenvalues λ_{i} of A have negative real parts.

In the example described, the eigenvalues of the system matrix A have negative real parts if the conditions

$$\psi = \frac{1}{\theta} + \alpha + \gamma + S \left(1 - \beta \frac{T_{\mathrm{A}}}{\bar{T}^2} \bar{a}\right) \mathrm{e}^{-T_{\mathrm{A}}/\bar{T}} > 0 \tag{3.3.25}$$

and

$$\varphi = \alpha + \gamma + S \left([\theta\,(\alpha + \gamma)] - p \frac{T_{\mathrm{A}}}{\bar{T}^2} \bar{a}\right) \mathrm{e}^{-T/\bar{T}} > 0 \tag{3.3.26}$$

are fulfilled. In this case the stationariness $\bar{a}$, $\bar{T}$ is asymptotic. Criteria of this type for the stability of linear systems can be generalized to arbitrary n-row system matrices A (e.g., the Hurwitz criterion) [257].

The transfer-function model associated with a time-invariant linear model is

$$y\,(t) = \int_{-\infty}^{t} K\,(t - \tau) \cdot u\,(\tau)\,\mathrm{d}\tau + D \cdot u\,(t) \tag{3.3.27}$$

The matrix $K(t)$ in Equation (3.3.27), known as the impulse response matrix, is given by

$$K(t) = C \cdot \mathrm{e}^{At} \cdot B \tag{3.3.28}$$

(For the definition of the matrix exponential function appearing in this formula, see [260].) If the system has no feed-through (i.e., $D = 0$), and the idealized impulse function $\delta(t)$ (delta function) is taken for $u(t)$, the result is

$$y(t) = \int_{-\infty}^{t} K(t-\tau) \cdot \delta(\tau)\,\mathrm{d}\tau = K(t) \tag{3.3.29}$$

$K(t)$ itself is thus the response when a unit impulse $\delta(t)$ is input to the system.

Because transfer-function models are often obtained from measurements alone, Equation (3.3.28) cannot be used to determine $K(t)$, since the matrices A, B, and C are unknown in these cases.

Example: The residence-time distribution of a continuous-flow apparatus is $w(t)$, and $w(t)\Delta t$ is the probability that a particle entering the apparatus at time $t_0 = 0$ leaves it in the interval $(t, t + \Delta t)$. By the superposition principle, the following relation is then obtained between the inlet flow rate u and the outlet flow rate y of an indicator substance:

$$y(t) \int_{-\infty}^{t} w(t-\tau) \cdot u(\tau)\,\mathrm{d}\tau \tag{3.3.30}$$

which is of the type of Equation (3.3.27) with $K(t) = w(t)$.

Accordingly, $w(t)$ can be found as the response to a unit impulse; this is a widely used method for residence-time distributions.

When time-invariant linear process models are investigated, the use of integral transformations is often very productive. The Laplace transformation, which is particularly important, is discussed only briefly here. This transformation, defined by

$$F(s) = \int_{0}^{\infty} \mathrm{e}^{-s \cdot t} \cdot f(t)\,\mathrm{d}t \tag{3.3.31}$$

assigns to the function $f(t)$, $t \geq 0$, a function $F(s)$ of the independent variable s. Here s can be taken as a complex variable; $F(s)$ is then differentiable (holomorphic) at least in the convergence region of the improper integral in Equation (3.3.31). The convergence region is a half-plane $Re(s) > \sigma$, with boundary $Re(s) = \sigma$ dependent on the function $f(t)$. To make the mapping property of Equation (3.3.31) especially clear, the notation

$$F(s) = L(f(t)) \tag{3.3.32}$$

is also used; $f(t)$ is then called the "original function" and the Laplace transform $F(s)$ is also called the "image function." Of the characteristics of the Laplace transformation, here only three that are particularly important for application to linear process models are mentioned:

1) The transformation is linear. From Equation (3.3.31) it follows that

$$\begin{aligned} &L(a_1 \cdot f_1(t) + a_2 \cdot f_2(t)) \\ &\quad = a_1 \cdot L(f_1(t)) + a_2 \cdot L(f_2(t)) \end{aligned} \tag{3.3.33}$$

2) The application of L to linear models thus preserves linearity.

$$L \cdot \frac{\mathrm{d}f(t)}{\mathrm{d}t} = s \cdot L(f(t)) - f(0) \tag{3.3.34}$$

3) If the convolution integral

$$\int_{0}^{t} f_1(t-\tau) \cdot f_2(\tau)\,\mathrm{d}\tau \tag{3.3.35}$$

is abbreviated as $f_1(t) * f_2(t)$, then

$$L(f_1(t) * f_2(t)) = L(f_1) \cdot L(f_2) \tag{3.3.36}$$

Equations (3.3.34) and (3.3.36), in particular, illustrate the simplifications that result from the use of the Laplace transform. Relatively complicated operations such as differentiation and convolution in the original domain turn into simple algebraic operations.

Computations with the Laplace transform can be schematized as shown in Figure 55. Correspondence tables, showing the original and transformed functions corresponding to a number of elementary functions, are employed. Consider, for example, the linear model

$$\dot{x} = a \cdot \mathrm{x} + b \cdot u \tag{3.3.37}$$

with initial condition $x(0) = x_0$. By using Equation (3.3.34):

$$s \cdot X(s) - x_0 = a \cdot X(s) + b \cdot U(s) \tag{3.3.38}$$

Figure 55. Application of the Laplace transformation

From this the following purely algebraic relation between the transforms X (s) *and* $U(s)$ is obtained

$$X(s) = \frac{x_0}{s-a} + \frac{b \cdot U(s)}{s-a} \tag{3.3.39}$$

Together with the correspondence $L(\mathrm{e}^{\mathrm{at}}) = 1/(s-a)$ and the property (Eq. 3.3.36), transforming (3.3.39) to the original domain directly gives the solution formula

$$x(t) = x_0 \cdot \mathrm{e}^{at} + \int_0^t \mathrm{e}^{a(t-\tau)} \cdot b \cdot u(\tau)\,\mathrm{d}\tau \tag{3.3.40}$$

For further details on the Laplace transformation, the reader should consult the specialist literature [283, 284].

The Laplace transformation can also be applied to vector-valued functions such as those appearing in the general model of Equations (3.3.17) and (3.3.18). Consider the case with no feed-through ($D = 0$). Application of the Laplace transformation gives

$$Y(s) = G(s) \cdot U(s) \tag{3.3.41}$$

which offers a simple link between the transforms $U(s)$ of the input and $Y(s)$ of the output in terms of the transfer matrix

$$G(s) = C \cdot (s \cdot I - A)^{-1}\,\mathrm{B}$$
$$(I = \text{identitymatrix}) \tag{3.3.42}$$

Note that, as usual, we are considering the state that depends only on the temporal behavior of n; that is, $x(0) = 0$ and Equation (3.3.41) holds only for inputs $u(t) = 0$ for $t < 0$. Equation (3.3.41) in the transform domain corresponds to the relation

$$y(t) = \int_0^t K(t-\tau) \cdot u(\tau)\,\mathrm{d}\tau \tag{3.3.43}$$

in the original domain, which follows from Equation (3.3.27) under the stated conditions. Thus the role of the impulse function response matrix $K(t)$ in the original domain is played by the transfer matrix in the transform domain.

A function of great importance in practice is the frequency response $G(j\omega)$, which is obtained by letting s take on imaginary values $j\omega$ (ω real) in Equation (3.3.42). The frequency response satisfies the fundamental relation

$$y(t) = G(j\omega) \cdot \mathrm{e}^{j\omega t} \cdot u_0 \tag{3.3.44}$$

which in the original domain gives a simple description of the response to periodic input functions $u(t) = e^{j\omega t} u_0$. Since the frequency response $G(j\omega)$ contains all the information about the process, an obvious way to extract this information is to measure the response functions $y(t)$ over an entire spectrum of input frequencies ω and use Equation (3.3.44) to determine $G(j\omega)$ from these. This "frequency response method" is also a highly sensitive procedure for stability analysis that does not require a knowledge of the system matrix A and its eigenvalues. The determination of the frequency response from measurements with the aid of periodic input functions also makes it possible to obtain the impulse response $K(t)$ more accurately than with the impulse method, even though the amount of measurement required is greater, since $K(t)$ is calculated from the frequency response $G(j\omega)$ through the inverse Fourier transformation:

$$K(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} G(j\omega)\,\mathrm{e}^{j\omega t} d\omega \tag{3.3.45}$$

This expression can be inverted in accordance with the Fourier integral formula:

$$G(j\omega) = \int_{-\infty}^{\infty} K(t)\, e^{j\omega t} dt \tag{3.3.46}$$

If the time dependence of the transfer function is replaced by a position dependence and, therefore, the temporal frequencies by spatial frequencies, the analogous operations lead to the contrast transfer function (optical transfer function) known from image transmission and photography. This function verifies the transformation principle described in Section 2.2 as well as the phase model derived from that principle in Section 2.3 [285].

3.4. Modeling

The derivation of a mathematical model for a given purpose involves several problems. The objective governs

1) The type of model (dynamic, time-continuous, time-discrete, stationary, time-variant, etc.)
2) The structure of the model (theoretical, statistical, transfer-function, linear, etc.)

The restrictions mentioned in Section 3.3, regarding the computability of the model and computing time problems, must also be taken into account. It is often not possible to give an a priori answer to the question of which physical processes should be incorporated into the model and which can be neglected. The addition of a further physical phenomenon to the model may render the former numerical method of solving the model equations useless and may lead to a large increase in total computing time. In such cases, attempts are made to use a simplified version of the model. Ultimately, however, the power of the model depends on the comparison of computed results with experimental data. The modeling process often becomes an iterative procedure in which calculation and experimentation alternate. It is not always the case that successive, improved versions of the model, when compared with the experimental data, will converge to the final model. Occasionally, new measurements are needed for deciding whether to accept or reject certain model assumptions.

These problems suggest a generalization of the problem statement: Given some competing models $M_1, M_2, \ldots$, describing a certain system, to find quantitative decision criteria for identifying the "best" model at minimal testing cost. A number of publications on this model discrimination problem have appeared [286–288]; in the well-known Box – Hill method [289], an entropy value is assigned to each model based on its agreement with previous experimental results, and the next test point is chosen so as to maximize the entropy difference between models.

Section 3.3 identified discretization as an essential step in obtaining finite-dimensional equivalent models of the type defined in Equations (3.3.1) – (3.3.3). This implies, in general, the problem of choosing the correct state variables in the vector x. Usually there is a wide range of options, and this transformational freedom should be utilized in mathematical models in order to exhaust certain optimization possibilities. The following main objectives can be stated:

- Models as small as possible
- Short computing times
- Model structures as simple as possible

These goals are interrelated and they also compete with the requirement of a minimum model accuracy. Known examples in which suitable coordinate transformations are used to give simpler model structures include the diagonalization of linear systems, with a diagonal matrix $\boldsymbol{A}$ as system matrix, and the change to dimensionless notation, which indeed often works wonders.

The requirement of small but efficient computational models must often be invoked, especially for on-line use. The model reduction or order reduction technique described here involves the replacement of a mathematical model by a smaller model. There are essentially two approaches

- The use of special physicotechnical properties of the system under consideration yields a reduced model that is often highly efficient
- The second approach consists of purely mathematically formal methods for obtaining reduced process models

In both procedures, a key role is played by the coordinate transformation concept. An attempt is made to position the new coordinate system so that the fewest possible coordinates

(state variables) are needed and so that these reflect the truly relevant degrees of freedom in the system. The technique involves projecting onto the state – space subspace that is essential for the processes taking place in the system. The idea is closely related to the principal-component analysis method used in Section 3.2 to spot relationships in existing data.

A well-known example of such a projection is the expansion in specified functions in the Ritz – Galerkin method. In this technique, eigenfunctions of the operator or so-called functions with compact support are employed in a finite-elements procedure. Other examples are Fourier series expansion; the method of moments used to solve systems of equations arising in, for example polymerization kinetics; and the use of symmetry properties generally. Mention should also be made of similarity theory [290–292], in which quantities relevant to the problem are determined, a dimensional analysis is performed, and the resulting set of dimensionless quantities is smaller in number than the dimensioned starting quantities.

Another example of order reduction is statistical mechanics, in which the ca. 10^{26} state variables that describe the ensemble of molecules in the subject system are projected onto a few new quantities, such as temperature, pressure, and enthalpy.

In the examples examined up to this point, either the transformations were physically motivated or plausible trial functions, series expansions, or the like were applied, and the coefficients in the expansions were taken as the new state variables. A number of methods have been devised [293–301] which attempt to eliminate this element of arbitrariness. In a certain class of transformations, these techniques identify the one for which a certain figure-of-merit functional is minimized.

Figure 56 illustrates the method schematically. Any reducible system has the following property: Every solution trajectory, after quickly passing through an initial branch, merges into a one-dimensional curve. This system therefore has just one relevant degree of freedom, even though it is two-dimensional. The discrepancy between the number of degrees of freedom n and the number of relevant degrees of freedom r is large for most large systems and represents the key to their reducibility. The appropriate coordinate transformation must be found so that z_1 will be the relevant state variable in the new coordinate system (as shown in Fig. 56) while z_2 plays a secondary role and can be neglected. If a certain set M of representative solutions $x(t)$ and associated solutions $x*(t)$ of the reduced system is chosen and the merit function

$$J = \sum_M \int_0^\infty \|x(t) - x^*(t)\|^2 \mathrm{d}t \tag{3.4.1}$$

[299] is examined, then for specified r the reduced system is defined such that J takes on a minimum value $J_{\min}$, whereby

$$e_{\min} = 100 J_{\min} / \sum \int_0^\infty \| \mathrm{x}(\mathrm{t}) \|^2 \mathrm{d}t \tag{3.4.2}$$

is a measure of the mean relative error of the solutions $x*(t)$ of the reduced system. Figure 57 shows $\varepsilon_{\min}$ as a function of the dimension of the reduced system r, where the original mathematical model was that of a distillation column with 33 trays and three components. The number n of differential equations is 68. The set of all response functions to step inputs was selected as the representative ensemble of solutions. The error $\varepsilon_{\min}$ decreases with increasing r, becoming zero for $r = 68$, where the unreduced original model is reached. Even for r as small as 4 the error is only ca. 0.5 %. Thus the problem requires a reduced model with only four differential equations instead of 68.

3.5. Management and Utilization of Information

Introduction. As early as 1986, the Association of Large Power Plant Operators (Verband der Grosskraftwerksbetreiber) carried out a thorough discussion of changes in process control engineering and the demands imposed on the management of engineering documentation [302].

With increasing complexity of plants and processes, the number of monitoring and control devices has increased out of proportion. The main reason has been the growing level of process automation. Rationalization has had little to do with this development; a far more important point is that stringent requirements on product quality not only call for increased information about the process but also demand more powerful process modeling aimed at better reproducibility and direct control of product quality. In addition, a keener awareness of plant safety has led to extensive safety analyses, which in turn have given rise to practices that frequently involve monitoring and control equipment.

These growing demands can easily bring about a documentation conflict between designers and builders of process plants, on the one hand, and operators and maintenance personnel, on the other. The management of data on control devices must enable the use of the documentation right through from concept, through design, execution planning, construction, and operation of the plant. The benefits of such an information

Figure 58. Example of a piping and instrumentation diagram (DIN 28 004, Part 1) [303]
B = belt conveyor; C = column; H = heat exchanger; M = motor; P = pump; S = separator; T = vessel, tank; V = valves; Z = size reduction; FRC = flow registration control; LRC = level registration control; TRC = temperature registration control

Figure 59. Example of a control system function diagram (DIN 40 719, Part 6)

system are not limited to rationalization; consistent documentation also simplifies the exchange of experience between operators and builders of plants.

Many discussions have contributed to the new edition of DIN 40 719, Part 2, ("Circuit Documentation: Labeling of Apparatus, Signals, and Documents"). The basic ideas can be extended in large part to the documentation of plant monitoring and control systems.

Forms of Organization. The classical organization of control engineering documents is functional (see Chap. 2). Documents are created in order to accomplish a certain task. The instrumentation of "something" is set forth in, for example, the piping and instrumentation diagram (Fig. 58). "Any" control system can be described by functional diagrams (Fig. 59) and schematic diagrams (Fig. 60) or program flowcharts. Documents for the installation of "any" process control device include schematics as well as terminal diagrams.

This type of documentation does fulfill its intended purpose, but it leaves the user virtually unable to form a comprehensive picture of the properties of the control system. Indeed, the user can hardly get an idea of the system from any other viewpoint than that of documents prepared in the past (see Section 2.2). As a consequence,

Figure 60. Example of an electrical schematic (DIN 40 719, Part 3)

Figure 61. A process control device (control station) from the design viewpoint: station (loop) diagram

No.	Control station KACP	Functions checked	Reason for check	Doc.reqd.?	Reqd. condition
1	V105 BA20 P2	I S + A +	Plant safety	Y	Shut down

Object-related instructions:
Written permission, station setup data sheet, station diagram required

Inspection: Check pressure measurement with I S + A + — Report

1. Perform visual inspection

   Are the elements of the process control station fully labeled, in good mechanical condition, and clean? — OK / OK after repair / Not OK

2. Connect mA test generator in place of transducer.

3. Check measuring range of readout at three points; note actual values.

Nominal values:	Test generator	Readout	Tolerance	Actual values
First value	4.0 mA	0.2 bar	± 0.02 bar	_____ bar
Second value	12.0 mA	0.6 bar	± 0.02 bar	_____ bar
Third value	20.0 mA	1.0 bar	± 0.02 bar	_____ bar

   Are the actual readout values within tolerance? — OK / OK after repair / Not OK

4. Check maximum limit indication.

   Limit: 0.90 bar — Tolerance: ± 0.02 bar

   When limit is exceeded, following indications must occur:

   Does visual indication "P02 max" occur in A 639 W 1 panel 7? — OK / OK after repair / Not OK

   Does acoustic indication occur in A 639 W 1? — OK / OK after repair / Not OK

5. Check maximum limit response.

   Limit: 0.95 bar — Tolerance: ± 0.02 bar

   When limit is exceeded, following responses must occur:

   Does valve P2 – Y1 open? — OK / OK after repair / Not OK

   Does pump P27 shut off? — OK / OK after repair / Not OK

6. Restore to initial condition.

Remarks: _____

Date: _____ Inspector's name: _____ ☐ Not inspected

Figure 63. Devices (DIN 40 719, Part 2)

whenever a new question arises, it is often necessary to create new supplementary documents even though these may contain scarcely any new information.

One remedy for this documentation bottleneck is object-oriented management of data on monitoring and control devices. Documents for a given task are then representations of object-related information, that is, projections from certain viewpoints (Figs. 61 and 62). Implementation of this concept requires, above all, the devising of a consistent data model for hardware

objects (see Section 2.2). It has proved desirable not to model the process control system in isolation but to see it as a component of the process plant.

The initial step must be to understand which data blocks are the fundamental ones. DIN 40 719, Part 2 defines the most important data blocks for electrical apparatus (Fig. 63).

This is not adequate for process plants, since it does not include the purpose of the facility: the process. Incorporating the process into the information structure becomes more important for process control engineering, the more use is made of higher process control functions such as recipe procedures and process models for process control (see Section 4.5).

It has proved desirable to separate detailed description of the engineering properties of a single instrument (substance) from information about its technical function (see also Section 2.3). This makes it possible to manage hardware improvements by replacing devices in the plant with others that perform the same function. All these aspects lead to an information structure for process plants and their process control systems as shown in Figure 64.

When an object-oriented model is created, these information blocks must be described interms of interlinked individual objects. Figure 65 presents a simplified example in which the "entity-relationship model" described in Chapter 2 was used.

When such a model has been set up, it is possible to file all information by object. For example, data on a process control station is filed only under that station. Data on a higher-order plant subunit are filed only under that subunit. They are automatically relevant to the lower-order control stations. Data on an apparatus or instrument type are filed only under that apparatus or instrument type. They are automatically relevant to the associated process control stations.

Application. After such a data model has been created (provided it is complete), documents can be generated at any time and tailored

Figure 68. Station (loop) diagram

to any objective. It is at least equally important that given information is managed by object, not in various documents. A computerized revision service can then be set up easily, so that information retrieved at any time will be internally consistent.

Flowsheets are now prepared for a plant (plant unit) or subunit in accordance with this data model (Fig. 66).

A functional diagram may refer to a certain subunit (Fig. 67) or to a certain control station (it is then known as a station or loop diagram; Fig. 68).

This object-oriented management of engineering data makes it possible to work with the same documentation at every stage of plant activity and to update the documentation step by step. A glance at the phases of plant activity (Fig. 69) shows the feasible and necessary level of detail in the documentation at each stage (see also Chap. 7).

Structuring of the processes in terms of unit operations (DIN 28 004) is possible and necessary even at the basic research stage. Plants can already be subdivided into units as documented in the basic flowsheet (Fig. 70). The assignment

Figure 69. Phases of plant activity

of unit operations to plant subunits, which is so important for higher-level automation tasks, can take place at this stage.

The phase model derived from experience in software engineering (discussed in detail in Section 2.3) is suitable for this purpose.

Quality assurance, in particular, calls for a systematic representation of product and process requirement profiles, since the needed data acquisition measures as well as sensor and actor systems must be established from this standpoint (Fig. 33). In this connection, the reader is referred to Japanese Industrial Standard JIS Z 8206-1982, "Graphical Symbols for Process Charts." This goes beyond DIN 28 004 by specifying which quantity and quality checks must be performed on product streams. More recent practice is to generate process control flowsheets and checklists as tools for quality assurance; these can also serve as evidence that the quality assurance system itself (Fig. 71) conforms to the standard.

The most important process control equipment is selected in the engineering design stage. Documentation relating to each control device, such as a control station, can be created here.

Of special importance in the approval planning (regulatory engineering) phase is the safety analysis, which establishes particular safety objectives and practices. It is important that all information used in this analysis refer to definite, documented engineering hardware (Fig. 72), since only then can the engineering of protective measures be assessed before commissioning and during plant operation.

At the stage of execution planning, all engineering details are fixed. The number of implementation options is unlimited in principle, but in any real enterprise the factors of economics and practicability call for the selection of procedures as well as instruments and systems with which, or from which, the requisite functions can be developed. These choices then lead to design and installation standards, but also to equipment and system standards. As discussed in Chapter 2 and at the beginning of this section, these decisions are also documented in the object-oriented framework (Fig. 73).

Figure 70. Basic flowsheet of a plant

Figure 71. Process monitoring flowsheet of a vulcanization accelerator (cf. JIS Z 8206)

Examples of activities during execution planning are the preparation of control station diagrams for process control devices and the specification of requirements on engineering properties. This information is filed and managed in the process control station. Realizable hardware units, for example, are handled as instrument types derived from the instrument standard, while the functional elements are assigned to control devices (Fig. 74). This has the great advantage that a distinction can be made between requirement and implementation and that, when instruments differing in type are interchanged, only the assignment must be changed. Manual updating of engineering details becomes unnecessary. Similarly, the basic functions of the process monitoring and control systems are assigned to the control devices. In addition to a more rational configuration, this offers the

advantage of greater reliability with regard to the consistency of engineering data (see Section 4.3).

Similarly, individual devices can be assigned by technical function if necessary. This would be the case, for example, if custom instruments were used instead of off-the-shelf devices, if the instruments were subject to individual inspection, or ifmaintenance cost records were to be kept for an individual unit.

Such assignments are important items of information for installation and maintenance. When necessary, they must be indicated locally. Maintenance and inspection work is classified by technical function (Fig. 75). The performance of such work and the results of inspections are documented by technical function. The analysis and repair of defects are done chiefly in reference to the technical function. In the course of examination, the engineering details on the assigned information can be considered; technical defects can be localized through the assignment of installation locations.

Such an information model makes possible an integral analysis of process facilities and, ultimately, of an entire company. The details of the model must be tailored to the technical circumstances. The storage and management of information in relation to engineering objects is crucial for its consistent use throughout the economic life of the plant. Only in this way is it possible to generate documents, at any time and at comparatively low cost, permitting instant analysis from any desired viewpoint.

4. From Process Knowledge to Process Control

4.1. Principles

Industrial processes, in contrast to natural processes, are artificially designed, consciously initiated, and purposely controlled so as to serve a certain end. It is not enough to understand an industrial process and be able to describe its internal dynamics in terms of a model; if the process is to take place at all, some form of external control is needed. This external control includes all functions required for coordinating and controlling the process. The structure, form, and implementation of these process control functions are the subject of the chapter that follows.

The sections on feedback control and optimal control set forth the most important design methods from control theory. Section 4.4 explains the concept of binary control in a variety of applications. In Section 4.5 it is shown how the operational control hierarchy can be structured for a plant as a whole. Process control functions play a central role in operational process control. For better understanding, these can be explained briefly before going on to the rest of the chapter.

Figure 76 shows schematically how process control functions work. The same diagram applies to all control functions. Each control function, on the basis of its own logic, seeks to bring the actual properties of a system into accord with the specified nominal properties. Each control function thus embodies certain assumptions about the behavior of the system. Using this knowledge, a control function can issue control commands in such a way as to influence the system in the desired fashion.

Figure 76. Schematic diagram of process control functions

In process control, the control variables and manipulated variables correspond to variable process or product properties. Manipulated variables either impinge directly on actuators or play the role of control variables, acting on lower-level control functions. In this way, process control can be built up in a hierarchical manner.

If we consider, for example, the adjustment of the pH in a reactor by the addition of acid, we obtain the hierarchy illustrated in Figure 77.

Figure 77. Schematic example of the hierarchy for a pH adjustment

The task of the production action is to make a product having certain properties at the discharge from the process section. For this purpose, one of the manipulated variables available to it for controlling the process is the pH in the vessel.

The metering device seeks to establish the specified time dependence of pH in the vessel; it therefore passes on the acid flow rate to the lower-level flow controller as a setpoint.

The flow controller, in turn, sets the required flow rate by specifying a certain valve position. The valve position controller exerts a corresponding control pressure to insure that the valve comes into the required position.

In most cases, a process control function has only one control variable; in general, however, m control variables and n manipulated variables must be allowed for.

The control concept can be customized for any process control function. The methods of control engineering are therefore applicable to process control functions at all levels in the hierarchy.

Process control functions can be classified in four groups by the concept employed:

1) Timed process control functions
2) Event-controlled feedback functions
3) Continuously controlled functions
4) Process control functions (optimized with respect to some quality criterion)

The selection of a concept depends less on the type of process control function and its position in the hierarchy than on the quality requirements, the anticipated severity of disturbances, the possibility of directly or indirectly measuring certain process properties, and (for the fourth group) the availability of suitable process models.

All the concepts are equally capable of reproducing a specified process if it is assumed that there are no disturbances.

Only when malfunctions or variations affect the course of the process will the four groups differ in their capabilities.

In practice, the concepts are combined as needed.

In what follows, the various concepts are illustrated for the case of a pH control. The task for the process control function is to regulate the addition of acid so as to keep the pH in a reactor at the proper value for the process.

Timed process control function: Acid is admitted to the reactor at a fixed, specified flow rate $q(t)$. If there are no disturbances, the desired pH value is established in the reactor. The actual pH value is not fed back.

Event-controlled feedback function: Acid is admitted to the reactor at a fixed, specified flow rate $q(t)$ until a certain specified pH has been reached; the flow is then cut off. If the process takes place without disturbances, the pH in the reactor follows the desired trajectory. If there are disturbances, the actual pH agrees with the desired pH, at least at the end point. The pH must be measured at least once.

Continuously controlled function: The admission of acid is controlled so that the pH in the reactor follows a fixed, specified control trajectory. Control actions compensate for upsets. Continuous pH measurement is required.

Optimal process control function: The control trajectory pH(t) is not specified in fixed form but is determined on the basis of the instantaneous process state and a quality criterion. If the fixed trajectory of concept 3 is assumed optimal in the sense of the quality criterion, functions 3 and 4 initially result in the same control trajectory. No difference is seen until a disturbance causes the actual value to depart from the nominal trajectory. Under concept 3, the control system attempts to force the process back onto the old trajectory; under concept 4, the process is guided along a new trajectory that is optimal when the actual situation is taken into account.

4.2. Feedback Control

Introduction. This section explains the concepts of feedback control and feedforward control. It discusses the distinction between the two as well as what process properties and what process requirements make a feedback structure necessary. The drawbacks to a feedback structure are also elucidated.

Any process is characterized by the action of the inputs on the outputs (Fig. 78). Inputs are classified as manipulated variables and disturbances. The former make it possible to intervene in the process, while the latter are undesired environmental effects that act on the process (see Chap. 3). Process outputs are quantities that are to be influenced in an appropriate way. Desired values for the outputs are called setpoints. Time-varying setpoints are called command or reference variables.

The objective of any control system is to interact with the process via the manipulated variables so as to insure stability and good performance.

Figure 78. Schematic diagram of a process

The second point means that the outputs should react in a desired fashion to a change in the setpoints (reference variables) or the disturbances. In particular, they should react sufficiently fast, and the steady-state difference between setpoints and outputs should be sufficiently small.

Feedforward control can be diagrammed as an open loop (Fig. 79). On the basis of externally specified setpoints and measured disturbances, the controller generates manipulated variables as process inputs. No check is made to determine whether the selected manipulated variables actually have the desired effect on the outputs. With this structure the objectives cited can be achieved only if

- All disturbances to the process can be measured
- The effets of control actions on the outputs are known with sufficient precision, so that the mathematical process model underlying the controller design reflects the main characteristics of the real process
- The uncontrolled process is stable (an unstable process cannot be stabilized by feedforward control)

Figure 79. Feedforward control

In contrast, good performance can often be achieved with feedback control (Fig. 80), even if the above requirements are not met. Some of the outputs to be influenced are measured and compared with their setpoint values. The differences between these values are transmitted to the controller, which uses them in calculating the required control actions. The drawbacks of a feedback control structure are that feeding back the outputs

- Introduces additional measurement errors
- May (if the controller is inappropriately designed) make a stable process unstable
- Fails to react to disturbances until after they have already influenced the outputs

Figure 80. Feedback control

In view of the last point, feedback and feedforward control concepts are often combined. An example is a feedback structure with an additional disturbance input to the controller (Fig. 81), in which measurable disturbances are partly compensated by feedforward control but in general they cannot be completely suppressed because of shortcomings in the mathematical process model. Feedback control is used in an attempt to diminish the "residual effects" of these disturbances, as well as the effects of unmeasurable disturbances on the outputs. The difficult aspect of such "mixed" concepts is generally the design of the feedback component. Therefore, the description in what follows will be restricted to this component. Detailed discussions of feedforward and feedback control concepts, along with analyses of their advantages and disadvantages, can be found in [304, 305].

Figure 81. Feedback configuration with additional feedforward control of disturbances

Characterization of Desired Control Loop Properties. Before discussing methods of control system design, it is necessary to explain some concepts required for characterizing properties of a control loop.

This section is limited to linear process models (see Section 3.3) and controllers. This restriction is justified in most cases because engineering processes often behave in an approximately linear fashion near the operating point and therefore can be handled by a linear controller. The deviation of the process behavior from the linearity of the model equation can then be treated as part of the model uncertainty, which must be taken into account in controller design anyway. It is also assumed that process model and controller are time invariant. The frequency response is then an ideal tool for investigating control loop properties.

Frequency Response. A linear, time-invariant system can be described by its frequency response $G(j\omega)$ (see Chap. 3). For a single-variable system (i.e., a system having one input and one output), $G(j\omega)$ is a complex-valued scalar, which can be graphically represented in either of two ways. First, it can be plotted in the complex plane for all (positive real) frequencies ω; this gives the Nyquist locus or polar plot of the frequency response. Second, the complex variable $G(j\omega)$ can be split into modulus (magnitude) $|G(j\omega)|$ and phase arg $[G(j\omega)]$ by polar decomposition,

$$G(j\omega) = |G(j\omega)|\, e^{j\arg[G(j\omega)]} \tag{4.2.1}$$

and each of these real quantities plotted separately as a function of ω. If logarithmic scales are used for frequency and modulus and a linear scale for phase, the result is the Bode plot of the frequency response. The modulus scale is usually multiplied by 20 and the unit of modulus is then the decibel: $|G(j\omega)|_{\mathrm{dB}} = 20 \log |G(j\omega)|$. Figures 82 and 83 show the polar plot and the Bode plot of the frequency response for a second-order lag element.

Figure 82. Nyquist locus or polar plot of frequency response

Figure 83. Bode plot

The frequency response has a straightforward physical explanation: If an asymptotically stable system characterized by $G(j\omega)$ is excited by a harmonic oscillation with frequency ω and amplitude $\hat{u}$ and the transients are allowed to decay, the output of the system oscillates harmonically at the same frequency, but with a phase shift φ and a different amplitude $\hat{y}$ (Fig. 84). The ratio of the output and input signal amplitudes (gain) and the phase shift between the two signals are described by the modulus and phase of $G(j\omega)$, respectively, and can thus be read directly from the Bode plot:

$$|G(j\omega)| = \hat{y}/\hat{u} \tag{4.2.2}$$

$$arg\,[G(j\omega)] = \varphi \tag{4.2.3}$$

Figure 84. Harmonic oscillations at the input and output of a linear time-invariant system

The frequency response is analyzed in detail in control engineering textbooks, for example, [304–306].

The requirements imposed on the closed control loop can be quantified with the aid of the frequency responses $G(j\omega)$ of the process and $K(j\omega)$ of the controller.

Stability. The Nyquist criterion represents a necessary and sufficient condition for the stability of a closed control loop [304, 307]. It requires that the Nyquist locus of the open-loop frequency response

$$Q(j\omega) := G(j\omega)\,K(j\omega) \tag{4.2.4}$$

encircles the "critical point" $(-1{,}0)$ $m/2$ times counterclockwise as the frequency ω goes from 0 to ∞, where m is the number of unstable poles of the open loop. Because the Nyquist locus of the example in Figure 85 encircles the critical point 1/2 times, the associated closed loop is stable if and only if either $G(j\omega)$ or $K(j\omega)$ (but not both) has one unstable pole.

Figure 85. Example of Nyquist stability criterion

Response to Reference Inputs and Disturbances; Noise Suppression. To determine whether a control loop exhibits good response to reference inputs and disturbances and has the ability to suppress measurements noise, it is necessary to examine how all quantities acting on the control loop from the outside (Fig. 86) influence the control error.

Figure 86. Linear feedback loop

The error $e(j\omega)$ is defined by

Figure 87. Typical shapes of $|S(j\omega)|$ and $|T(j\omega)|$

$$e(j\omega) := r(j\omega) - y(j\omega) \tag{4.2.5}$$

Hence

$$e(j\omega) = \underbrace{\frac{1}{1 + G(j\omega)\,K(j\omega)}}_{S(j\omega)}[r(j\omega) - d(j\omega)] + \underbrace{\frac{G(j\omega)\,K(j\omega)}{1 + G(j\omega)\,K(j\omega)}}_{T(j\omega)}\eta(j\omega)$$

The quantity $S(j\omega)$ is called the sensitivity function, because it gives the sensitivity of the control error to a disturbance acting on the output and to the reference variable. $T(j\omega)$ is known as the complementary sensitivity function. The objective is to keep $|S(j\omega)|$ and $|T(j\omega)|$ small, and thus to achieve a small gain between quantities acting on the control loop from outside and the control error. Unfortunately, this is generally impossible, since for any ω

$$S(j\omega) + T(j\omega) = 1 \tag{4.2.7}$$

This "fundamental dilemma" of control engineering, embodied in Equation (4.2.7), is often alleviated because in most casses reference variables and disturbances contain mainly low-frequency components and hence vary comparatively slowly with time, while measurement noise commonly occurs at high frequencies. It is then sufficient to make $|S(j\omega)|$ small at low frequencies and $|T(j\omega)|$ small at high frequencies. Figure 87 shows typical plots of the sensitivity and complementary sensitivity functions. The bandwidth ω_b of the closed loop is the frequency above which

$$|T(j\omega)| < 0.708 \text{or} |T(j\omega)|_{dB} < -3 \tag{4.2.8}$$

It "separates" the frequency range in which the closed loop has good response to reference inputs and disturbances from the frequency range in which measurement noise is suppressed. Establishing the desired bandwidth is thus one of the most important decisions in any controller design problem.

Robustness. The discussion up to this point has had to do with how to insure desired properties for the "nominal" control loop (i.e., the system consisting of process model and controller). The objective is to transfer these properties to the real control loop (the system consisting of the real process and the controller). In this context, robustness means that the properties of the nominal control loop should be robust with respect to errors in the model.

Robustness can be investigated only if an upper boundary can be given for the size of the model error. Often an upper bond for the relative model error is estimated by assuming that the real process behaves in a linear and time-invariant fashion near the operating point under consideration. The (unknown) frequency response of the process is represented by $G_r(j\omega)$. If the known frequency response of the model is $G(j\omega)$, the relative model error is then defined by

$$\Delta(j\omega) = \frac{G_r(j\omega) - G(j\omega)}{G(j\omega)} \tag{4.2.9}$$

Suppose the modulus of the relative model error is bounded by a known real-valued and positive function $p(j\omega)$:

$$|\Delta(j\omega)| < p(j\omega) \tag{4.2.10}$$

Figure 88 shows a typical curve of $p(j\omega)$, which grows rapidly with increasing frequency.

Figure 88. Typical error bound

If G_r and G have the same number of unstable poles, it is easy to show [308] that the stability of the control loop is robust to all model errors permitted by Equations (4.2.9) and (4.2.10) if and only if the following holds for the nominal complementary sensitivity function

$$|T(j\omega)| < \frac{1}{p(j\omega)} \tag{4.2.11}$$

To achieve good performance of the real loop the nominal sensitivity function must usually be made sufficiently small at low frequencies while the nominal complementary sensitivity function must be sufficiently small in the frequency range where the model uncertainty is large (see Fig. 88) [309].

Open-Loop Shaping. The Nyquist criterion makes it possible to guarantee closed-loop stability by appropriate manipulation of the open-loop frequency response $Q(j\omega)$. The sensitivity function and the complementary sensitivity function are used to guarantee the other control-loop properties stated. Since both quantities depend on Q in a simple way (see Eq. 4.1.6), all the desired properties of the control loop can be achieved by suitable "shaping" of the open-loop frequency response $Q(j\omega)$. The term "open-loop shaping" is often used in this context. Good response to reference inputs and disturbances thus requires that

$$|Q(j\omega)| >> 1 \tag{4.2.12}$$

at low frequencies, whereas suppression of measurement noise requires that

$$|Q(j\omega)| << 1 \tag{4.2.13}$$

at high frequencies. In the region near the gain crossover frequency ω_d, however, $|Q(j\omega)|$ must not roll off too rapidly. (The gain crossover frequency is the frequency at which $|Q(j\omega)|$ intersects the 0 dB line.) Otherwise, disturbances, reference variables, and measurement noise can produce large control errors in this frequency range. Moreover, rapid gain roll-off near the crossover frequency threatens closed-loop stability. This is a direct consequence of the Bode gain – phase relation [304, 310]. The ideal would be a 20 dB per decade roll-off for $|Q(j\omega)|$ in this frequency range. If this is the case, the gain crossover frequency ω_d is a good approximation to the bandwidth ω_b of the closed loop.

Multivariable Systems. The discussion to this point has related only to systems with one input and one output. Most industrial processes, however, have multiple manipulated variables and multiple outputs to be suitably influenced. Each of the manipulated variables will, in general, affect several or even all of the controlled variables. The process is then said to be a multivariable (multi-input, multi-output) system, and its dynamics (assuming linearity and time-invariance) are described by the frequency response matrix

$$G(j\omega) = \begin{bmatrix} G_{11}(j\omega) \cdots G_{1q}(j\omega) \\ \vdots \qquad\qquad \vdots \\ G_{p1}(j\omega) \cdots G_{pq}(j\omega) \end{bmatrix} \tag{4.2.14}$$

Most of what has been discussed up to now can be extended to multivariable systems with no difficulty.

The multivariable Nyquist criterion is a necessary and sufficient condition for the stability of the closed loop. It requires that the frequency-dependent eigenvalues of the matrix $Q(j\omega)=G(j\omega)K(j\omega)$ (the"characteristic loci"), taken together, encircle the "critical point" $m/2$ times [311, 312].

To assess the other control-loop properties, the concept of gain must be generalized [313]. In the single-variable case, the gain of an asymptotically stable system corresponds to the modulus of the frequency response. The situation is somewhat more complicated in multivariable systems. Such a system has a gain that depends on the direction of the input vector. The gains of most interest are the minimum and maximum (frequency-dependent) gains. These are characterized by the minimal and maximal singular values of the frequency response matrix:

Figure 89. Bode plot of a lead compensator

Figure 90. Bode plot of a lag compensator

Figure 91. Bode plot for $Q(j\omega)$ in the example

$$\min_{u\neq 0}\frac{\|y(j\omega)\|}{\|u(j\omega)\|}=\sigma[G(j\omega)]$$
$$=\sqrt{\lambda_{\min}[G^T(-j\omega)G(j\omega)]} \tag{4.2.15}$$

$$\max_{u\neq 0}\frac{\|y(j\omega)\|}{\|u(j\omega)\|}=\bar{\sigma}[G(j\omega)]$$
$$=\sqrt{\lambda_{\max}[G^T(-j\omega)G(j\omega)]} \tag{4.2.16}$$

Here $\|\ldots\|$ denotes the Euclidean vector norm (see Chap. 3), while $\lambda_{\min}$ and $\lambda_{\max}$ are the smallest and largest eigenvalues.

With these gains, the requirements derived for single-variable systems can readily be extended to the multivariable case [308]:

$$\bar{\sigma}[S(j\omega)]<<1 \text{ or } \sigma[Q(j\omega)]>>1 \quad \text{for} \quad \omega<<\omega_{\mathrm{b}} \tag{4.2.17}$$

$$\bar{\sigma}[T(j\omega)]<<1 \text{ or } \bar{\sigma}[Q(j\omega)]<<1 \quad \text{for} \quad \omega>>\omega_{\mathrm{b}} \tag{4.2.18}$$

The sensitivity matrix S and the complementary sensitivity matrix T are defined similarly to the scalar variables in the single-variable case: $S:=(I+GK)^{-1}$ and $T:=(I+GK)^{-1}GK$.

If the requirements on the various controlled variables differ sharply, frequency-dependent weighting matrices for S, T, and Q can be used to handle the situation.

Controller Design Methods. This section surveys the most important methods of controller design.

Classical Control Engineering. The methods of classical control engineering continue to be dominant in many areas. In general, these methods assume a linear, time-invariant, single-variable process model. If the requirements on the controlled system are not too stringent, however, these methods can still be used in many cases even where such models give a highly erroneous description of the real process.

The most important design method in classical control engineering is the frequency response method [304,306,314]. It has the objective of shaping the open-loop frequency response $Q(j\omega)$ in accordance with what was said in the preceding section. For this purpose compensators

$$K(j\omega) = k\frac{1 + j\omega T_1}{1 + j\omega T_2} \tag{4.2.19}$$

are connected in series with the process. The compensator increases the phase if $T_1 > T_2$ (lead compensator) and decreases it if $T_2 > T_1$ (lag compensator); see Figures 89 and 90. A special case of the lag compensator for $k = \tilde{k}T_2$ and $T_2 \to \infty$ is the proportional-plus-integral (PI) element. Because of the particular axis scaling, the Bode diagram of a series system can be obtained by simply adding the amplitude and phase curves of the individual elements. It is thus easy to see what kind of compensating network is required to modify the curves in the desired way. For example, Figure 83 shows the frequency response of a process model; the bandwidth of the closed loop is required to be $\omega_b = 1$. In this case a PI element with frequency response $K(j\omega) = (1 + 0.1j\omega)/j\omega$ can be used as the compensator. The resulting amplitude and phase plots for the open loop are shown in Figure 91. Clearly, $Q(j\omega)$ satisfies requirements of Equation (4.2.12) at low frequencies and of Equation (4.2.13) at high frequencies. The polar plot of $Q(j\omega)$ can be used to check whether the Nyquist criterion is also satisfied. Figure 92 shows the curve near the origin. The quantities ϕ_r ("phase margin") and a_r ("gain margin") give the "distance" at which the polar plot of the frequency response passes the critical point (i.e., how "close" the loop is to instability). The gain and phase margins can also be read directly from the Bode plot in Figure 91. The following can serve as a rule of thumb for the use of the frequency-response method: $a_r > 2.5$ or $|a_r|_{dB} > 8$ and $\phi_r > 30°$. Because the gain and phase margins in this example are sufficiently large, a further compensation of $Q(j\omega)$ can be dispensed with.

Figure 92. Polar plot for $Q(j\omega)$ in the example

Figure 93. Classification of methods in control theory

Another widely used technique is the root-locus method [304,307,314]. This design procedure starts not with the frequency response, but with the transfer function of the plant (process) model. The location of poles and zeroes of this transfer function indicates how the poles, and thus the dynamics of the closed loop, vary as a function of the controller parameters and structure. This method is accordingly suitable for insuring the stability of the control loop. On the other hand, it generally proves quite difficult

to insure other desired properties of the control loop. Another disadvantage of this design technique it that it cannot be applied to process modes with time delays.

In process engineering, a controller structure (PID) is often specified and the parameters are obtained by experimenting on the process and evaluating the Ziegler – Nichols rules [307, 314]. When such a procedure is used in practice, there is no need for an explicit process model; the theoretical justification, however, presumes the existence of linear, time-invariant single-variable models.

Discarding one or more of the three model assumptions in classical control engineering leads to the other three (overlapping) "classes" of control engineering (Fig. 93).

Table 2. Multivariable design method

Time-domain	Frequency domain	
	Direct Nyquist array method	
	Inverse Nyquist array method

LQG method	H_2 Minimization	
Pole assignment	H_∞ Minimization	Closed-loop shaping
	IMC method	

Multivariable Control. Of the three model assumptions in classical control theory, the one furthest from reality is usually that the process can be described in terms of several independent single-variable models. Ignoring the links between various manipulated and controlled variables can lead to major problems: input controllers that work against one another (wasting energy) and instability of the controlled process may result. Design methods that take account of the links and thus the multivariable structure of the control loop exist in both the frequency and the time domains. Frequency domain methods begin with a transfer or frequency response matrix as the plant model; time-domain methods are based on state-space models (see Chap. 3). The frequency-domain methods can be classified in two groups: generalizations of the classical frequency-response method, in which an attempt is made to manipulate the open-loop frequency response matrix $Q(j\omega)$ in an appropriate way (open-loop shaping), and approaches that seek to influence directly, or optimize, the closed-loop frequency response matrices (closed-loop shaping). Table 2 lists the most commonly used linear, time-invariant multivariable design met ods. Some of these techniques are fully described in textbooks of multivariable control engineering [312, 315–318].

The LQG (linear quadratic Gaussian) method is based on a linear, time-invariant state-space model (see Chap. 3) of the control loop:

$$\dot{x}(t) = Ax(t) + Bu(t) + w(t) \tag{4.2.20}$$

$$y(t) = Cx(t) + v(t) \tag{4.2.21}$$

where $w(t)$ and $v(t)$ are error terms representing, respectively, disturbances and measurement noise acting on the plant. They are modeled as white (Gaussian) random processes with a mean of zero [319, 320]. Their spectral densities P and R provide a measure of the "strength" of these random processes. They tell how dependable the deterministic components of the models are. If the goal is to keep the plant as close as possible to the operating point $x = 0$, subject to a restriction on the use of control energy, then it is desirable to seek a control strategy that will minimize the cost function

$$J = E\left[\int_0^\infty \left(x^T L x + u^T M u\right) \mathrm{d}t\right] \tag{4.2.22}$$

The (positive semidefinite) matrix L penalizes deviations of the state variables from zero, and the (positive definite) matrix M penalizes the control energy. The symbol E represents the expected value. This problem can be solved straightforwardly. The separation principle states that the problem can be approached in two independent steps:

– First, ignore the fact that the state is not measurable and suppose it is exactly known. The optimal control strategy is then a constant state feedback:

$$u(t) = -K_c x(t) \tag{4.2.23}$$

Here K_c can be uniquely calculated from the model matrices A and B and the weight matrices L and M.

– In the second step, determine an optimal (in the sense of minimum error variance) estimate $\hat{x}$ for the unmeasurable state vector x. This is done by the use of a Kalman – Bucy filter [319,321] (Fig. 94). The Kalman – Bucy filter includes the deterministic part of the plant model and thus attempts to simulate the behavior of the state variables. What is more, however, the model also receives measurement information y, which is used for correcting the estimate (unless it agrees with the measurement $\hat{y}$ predicted by the model internal to the filter). The filter matrix K_f that specifies this correction is uniquely determined by the matrices A and C of the deterministic model component and the spectral densities P and R of the stochastic component. The optimal control strategy is now to replace the true state x in Equation (4.2.23) by the estimate $\hat{x}$.

Figure 94. Kalman – Bucy filter

The derivation and details can be found in, for example, [322,323]. Despite its theoretical elegance, the use of the LQG method in practice commonly presents problems. In chemical engineering, state – space models rarely have a simple physical interpretation. Generally, one has to be content with simple frequency-domain models (transfer function matrix, frequency response matrix) derived from the input/output behavior of the real process. While these state – space models can be determined from such input – output models their state variables then often fail to correspond to physically relevant quantities. This fact makes it difficult to determine a suitable weighting matrix L. Finding the spectral densities (especially for the "system noise" w) may well prove to be a matter of luck as well. In such cases, the elements of P and L offer a large number of design parameters whose effects on the desired control-loop behavior are difficult to assess.

One way of avoiding this problem is the LQG/LTR (loop transfer recovery) design method [318,324], in which the design parameters P, R, L and M of the LQG design are divorced from any physical meaning and selected such that the open-loop frequency response matrix $Q(j\omega)$ satisfies the requirements stated in the preceding section. For this reason, the LQG/LTR design technique is often classified as a frequency-domain method.

A further time-domain method is pole assignment [307,315]. It has the objective of specifying the poles and thus the dynamics of the closed loop by means of appropriate state feedback. If the state is not measurable, it is estimated by a Luenberger observer. The Luenberger observer resembles the Kalman – Bucy filter in that it is an algorithm for reconstructing the system state and in that it contains a model of the plant. It differs from the filter only in the way the correction matrix K_f is computed. In the case of the observer, this is done by specifying the dynamics of the equation for the estimation error. There is again a kind of separation principle in pole assignment: the observer matrix K_f and the state-estimate matrix K_c can be designed independently. The use of this technique may also create problems if the state variables have no direct physical meaning. Furthermore, establishment of the control-loop dynamics does not guarantee satisfactory loop behavior.

The characteristic locus curve method [325] seeks to meet the requirements stated in the preceding section by manipulating the eigenvalues of the open-loop frequency response matrix $Q(j\omega)$. These eigenvalues $\lambda_{Qi}(j\omega)$ are called "characteristic frequency responses." If the corresponding eigenvectors are collected in the matrix $V(j\omega)$, the following holds

$$Q(j\omega) = V(j\omega)\,\mathrm{diag}\left\{\lambda_{Qi}(j\omega)\right\} V^{-1}(j\omega) \tag{4.2.24}$$

Spectral decompositions for the sensitivity matrix and the complementary sensitivity matrix are then given by

$$S(j\omega) = V(j\omega)\,\mathrm{diag}\left\{\frac{1}{1+\lambda_{Qi}(j\omega)}\right\} V^{-1}(j\omega) \tag{4.2.25}$$

$$T(j\omega) = V(j\omega)\,\mathrm{diag}\left\{\frac{\lambda_{Qi}(j\omega)}{1+\lambda_{Qi}(j\omega)}\right\} V^{-1}(j\omega) \tag{4.2.26}$$

The eigenvalues of S and T thus depend in a very simple way on the $\lambda_{Qi}(j\omega)$. Although the gains of a matrix cannot be deduced from the absolute values of its eigenvalues, these do serve as a good indication of the gains in many cases. Therefore, small $|\lambda_{Qi}(j\omega)|$ at high frequencies and large $|\lambda_{Qi}(j\omega)|$ at low frequencies are required. The crossover frequencies for the characteristic frequency responses are selected to correspond to the desired closed-loop bandwidth. What is more, the multivariable Nyquist criterion makes it possible to say how often the locus curves of $\lambda_{Qi}(j\omega)$ (the "characteristic locus curves") must enclose the critical point $(-1,0)$ for the (nominal) control loop to be stable. Once the characteristic frequency responses have been chosen, the behavior of $\bar{\sigma}[S(j\omega)]$ and $\bar{\sigma}[T(j\omega)]$ must be examined to ensure that Equations (4.2.17) and (4.2.18) are satisfied. Now a way must be found to modify the characteristic loci in the desired way. The ideal method is to use a controller frequency response matrix having the same eigenvectors as the plant frequency response matrix. The following would then hold:

$$Q(j\omega) = \underbrace{V \text{ diag}\{\lambda_{Gi}(j\omega)\} V^{-1}}_{G(j\omega)} \underbrace{V \text{ diag}\{\lambda_{Ki}(j\omega)\} V^{-1}}_{K(j\omega)} = V(j\omega) \text{ diag} \underbrace{\{\lambda_{Gi}(j\omega)\lambda_{Ki}(j\omega)\}}_{\approx \lambda_{Qi}(j\omega)} V^{-1}(j\omega) \tag{4.2.27}$$

In this case, the $\lambda_{Gi}(j\omega)$ could be treated as single-variable systems, and suitable single-variable controllers $\lambda_{Ki}(j\omega)$ could be designed by the classical frequency-response method. Unfortunately, this is rarely possible, because the elements of V are generally nonrational in $j\omega$, and the resulting controller matrix thus cannot be realized. One therefore has to be content with approximating the ideal controller by approximating the complex matrices $V(j\omega_i)$ with real matrices for selected frequencies ω_i.

A shortcoming of the characteristic locus method is that the $|\lambda_{Qi}(j\omega)|$ provide only an indication of the actual gains of $Q(j\omega)$. In the RFN (reversed-frame normalizing) method [326], attempts are made to bring the absolute values of the eigenvalues and the gains (singular values) of $Q(j\omega)$ into coincidence. If this is successful (approximately), all the conditions stated in the preceding section can be met through manipulation of these quantities. A drawback of the characteristic locus and RFN methods is that the characteristic frequency responses cannot be associated with individual plant input and output variables. There is accordingly no systematic way of making different controlled variables display different transient responses or different steady state accuracy. Such difficulties are less pronounced (or nonexistent) in the methods discussed below.

The direct Nyquist array method [311] breaks the design process into two steps:

1) First, an attempt is made to approximately diagonalize the plant model by means of a simple – and, if possible, constant – compensator K_c. This means that off-diagonal elements of the frequency-response matrix should be small in magnitude compared to the diagonal elements. In particular, if the elements of the compensated $p \times p$ matrix $Q_c = GK_c$ satisfy

$$\sum_{k=1,k\neq i}^{p} |Q_{C_{ki}}(j\omega)| < |Q_{C_{ii}}(j\omega)| \tag{4.2.28}$$

for $i = 1, \ldots, p$ and $0 \leq \omega < \infty$, then $Q_c(j\omega)$ is said to be (column-)diagonal-dominant. The diagonal-dominance of a frequency-response matrix can easily be checked graphically. The polar plots of the diagonal elements $Q_{c^{ii}}(j\omega)$ are overlaid with circles whose radii are given by the left-hand side of Equation (4.2.28). The bands formed by these circles are called Gershgorin bands. If Equation (4.2.28) is satisfied, these bands do not cover the origin of the complex plane. A number of methods have been advanced for obtaining narrow Gershgorin bands [311, 315, 318].

2) In the second step, the small off-diagonal elements of Q_c are ignored. Single-variable controllers $K_i(j\omega)$ are designed for the principal diagonal elements of the compensated plant

Figure 95. Gershgorin bands for a 2×2 system

model Q_c; thus the open-loop frequency-response matrix is obtained:

$$Q(j\omega) = \underbrace{G(j\omega)K_c(j\omega)}_{Q_c(j\omega)} \text{ diag}\{K_i(j\omega)\} \quad (4.2.29)$$

This operation alters the form of the Gershgorin bands but leaves their width unchanged, since both the center and the radius of each Gershgorin circle are multiplied by the same factor. The Gershgorin bands of $Q(j\omega)$ make it possible to assess the stability of the closed loop, since they contain the characteristic loci curves. If the bands do not cover the critical point (−1,0), they determine how many times the characteristic locus curves encircle this point. Accordingly, the $K_i(j\omega)$ must be chosen such that the Gershgorin bands of Q do not cover the point (−1,0) and, collectively, they encircle this point counterclockwise $m/2$ times. Figure 95 shows an example for $m = 0$. To perform a classical single-variable design for the i-th controller component, the corresponding frequency-response element of the compensated plant model also must be known for the case where the remaining control loops are already closed. Because small off-diagonal elements are still present, this frequency response will not coincide with $Q_{c^{ii}}$. Its polar plot, however, lies in the interior of the Gershgorin band associated with $Q_{c^{ii}}$. This is a further reason for the importance of narrow Gershgorin bands.

Experienced users generally prefer the inverse Nyquist array method [311], which has the advantage that the relationship between $y_i(j\omega)$ and $u_i(j\omega)$ becomes sharper when the other control loops are closed. This relationship is localized by Ostrowski bands, which lie in the interior of the Gershgorin bands. The method has the disadvantage that it entails the use of inverse frequency responses. Furthermore, the technique can be applied only to systems in which the number of manipulated variables equals the number of controlled variables.

A design method that has been gaining popularity in the process engineering field is the IMC (internal model control) technique [327]. In its simplest form, this method assumes a stable plant. The controller then contains a plant model in parallel with the actual plant (Fig. 96). The requirements on the closed control loop are easily fulfilled with this structure, because

1) The closed loop is stable if and only if the controller component $\Gamma(j\omega)$ is stable
2) The sensitivity matrix and the complementary sensitivity matrix depend on Γ in a very simple way:

$$S = I - G\Gamma$$
$$T = G\Gamma \quad (4.2.30)$$

Figure 96. IMC structure

Figure 97. Hierarchical and decentralized control structures

A promising approach to the design of multivariable controllers is H_∞ minimization [328, 329]. The discussion in the preceding section showed what kind of behavior should be sought for the maximum singular values of the sensitivity matrix and the complementary sensitivity matrix. In addition, the matrix $K(j\omega)S(j\omega)$ can be included in the analysis. This matrix indicates how disturbances in the control loop affect the manipulated variables (see Fig. 86). Typically, $\bar{\sigma}[K(j\omega)S(j\omega)]$ is required to be bounded for all frequencies. This is intended to prevent the manipulated variables being saturated when disturbances occur. To avoid high-frequency oscillation of actuators, a further requirement is that $\bar{\sigma}[K(j\omega)S(j\omega)]$ roll off at high ω. For S, T, and KS to have small gains, each in its own frequency range, distinct frequency-dependent weighting matrices W_S, W_T, and W_KS are assigned to them. A controller is then sought that stabilizes the control loop and minimizes

$$\sup_\omega \bar{\sigma} \begin{bmatrix} W_\mathrm{S}(j\omega)S(j\omega) \\ W_\mathrm{T}(j\omega)T(j\omega) \\ W_\mathrm{KS}(j\omega)KS(j\omega) \end{bmatrix} := \left| \begin{matrix} W_\mathrm{S}S \\ W_T T \\ W_\mathrm{KS}KS \end{matrix} \right|_\infty \quad (4.2.31)$$

$\|\ldots\|_\infty$ is known as the H_∞ norm. Algorithms for solving this problem are complex and computationally intensive. For the user, however, this point is usually of as little importance as the nonuniqueness of the solution. The design engineer need only select the weighting matrices. As a rule, they are chosen to be diagonal matrices with stable, minimum-phase elements. Low-pass elements are commonly used for weighting S, so that small $\bar{\sigma}[S]$ is obtained at low frequencies. Similarly, high-pass elements are used for weighting T and KS. This method has the considerable advantage that the elements of the weighting matrices can be directly assigned to distinct manipulated and controlled variables. Their effect on closed-loop behavior is thus easy to assess. The selection of weights is illustrated in page 86.

Decentralized and Hierarchical Control. When the known multivariable methods are used, difficulties arise if the process to be controlled has many coupled inputs and outputs. Such large-scale systems should be broken down into subproblems. This can be done heuristically (and the subproblems defined, for example, as physical parts of the plant) or by means of formal techniques (e.g., the block relative-gain array [330]). A (multivariable) controller is assigned to each subsystem; in the design of this controller, however, links between the subsystems cannot be completely neglected. If the controllers operate independently of one another, this is known as decentralized control; if they are coordinated at a higher level, the control scheme is said to be hierarchical (Fig. 97) [331–335]. Most known hierarchical and decentralized methods belong to the time domain. With regard to their use in practice, essentially the same problems arise as in the LQG or pole assignment methods. The development of frequency-domain decentralized and hierarchical methods promises to be helpful.

Adaptive and Nonlinear Control. Linear control methods reach their limits in processes having no operating point or a continuously variable operating point (batch processes).

Conceptually, the simplest way of dealing with problems involving an operating point that varies slowly over time is to use adaptive control [336, 337]. Adaptive controllers continuously modify themselves to match the process being controlled. In general, only the simplest class of adaptive methods are employed in practice: self-tuning controllers. An indirect variant of such a controller is made up of a three-level algorithm: on-line estimation of parameters of a process model with specified (usually linear) structure; calculation of parameters for a controller structure, also specified; and action of the resulting controller on the process (Fig. 98). In this way, the entire (nonlinear) control problem is broken down into an estimation problem and a straightforward, generally linear, control problem. Adaptive control structures can therefore be treated as special nonlinear control structures.

If the operating point of the process changes very rapidly or a linear description is altogether impossible, explicitly nonlinear methods must be considered. However, these methods, such as exact linearizaton [338], are restricted to a very small class of nonlinear systems. Exceptions are semi-heuristic methods such as nonlinear versions of MPC (model predictive control) [339].

Figure 98. Self-tuning controller (indirect)

Design Aids. Most modern design techniques are so complex that they could not be employed without the help of suitable CACSD (computer-aided control systems design) packages. A continuously updated survey of available software is the ELCS (Extended List of Control Software) [340]. A further summary can be found in [341].

Design Example. This section shows how the classical frequency-response method and H_∞ minimization can be used in the design of controllers for a pilot-plant distillation column with 40 trays (Fig. 99). The device separates a mixture of methanol and propanol. The control objective is to keep the concentrations constant in the bottoms and distillate as the feed rate or feed concentrations change. As is common in binary separations, the concentrations and temperature on an individual tray are related in a unique way. Instead of the concentrations, which are difficultto measure, the temperatures can therefore be controlled. Simulation studies based on a detailed nonlinear model (using the DIVA simulation system [342]) have shown that the temperatures on the 14th and 28th trays are most sensitive to disturbances in the feed. These two temperatures are therefore chosen as controlled variables. The manipulated variables are the heat input Q_E and the reflux ratio $\varepsilon = L/V_K$. The controller design is based on a simple linear model obtained by evaluating step responses:

$$\begin{bmatrix} \Delta T_{14} \\ \Delta T_{28} \end{bmatrix} = \underbrace{\begin{bmatrix} -\dfrac{1220}{6.1j\omega+1} & \dfrac{100}{(1.2j\omega+1)(1.5j\omega+1)} \\ -\dfrac{1500}{2.7j\omega+1} & \dfrac{324}{1.6j\omega+1} \end{bmatrix}}_{G(j\omega)} \begin{bmatrix} \Delta\varepsilon \\ \Delta Q_E \end{bmatrix} \tag{4.2.32}$$

Here Δ denotes deviations of the indicated quantities from the desired stationary operating condition. The time constants of the model are given in hours. The most important specification for linear controller design is the closed-loop bandwidth, which should be close to $40\,\mathrm{h}^{-1}$.

Figure 99. Distillation column
V_K = vapor stream; L = reflux stream; D = distillate; Q_E = heat input rate

In the classical frequency-response method, the off-diagonal elements are neglected and only the diagonal elements of G are considered. Figure 100 shows the magnitudes for these elements. To suppress steady state errors PI controllers are used. Their time constants are selected such that the magnitude of both elements rolls off at a rate of ca. 20 dB per decade over the whole frequency range. The controller gains are set so that the two magnitude curves coincide over a broad frequency range and the bandwidth

of the closed multivariable control loop takes on the desired value. The last point is verified by computing the singular values of the complementary sensitivity matrix (Fig. 101).

In the H_∞ minimization method, weight matrices are selected for *S, T*, and *KS*. Diagonal matrices with minimum-phase elements are employed. Figure 102 shows the amplitude characteristics of the elements of W_S (low-pass) and W_T (high-pass). All elements are chosen such that their gains intersect the 0 dB line at 40 h^{-1}, because closed-loop bandwidth should lie close to this frequency. Small constants (0.01) are chosen as diagonal elements of W_{KS}, since in this example no problems with actuator saturation or high-frequency actuator oscillation are expected. The H_∞ cost function is completely defined in this way. It is minimized by a controller of order eight, but this can be reduced to order 5 by model reduction techniques. Figure 103 gives plots of the singular values of *S* and *T*.

Both controllers were tested in a pilot plant. It was found that the controller obtained by minimization of H_∞ met all practical requirements, while the classical PI controller required on-line tuning of the gains.

Details and comparisons with other multivariable design methods can be found in [343].

4.3. Optimal Control

Introduction. Before something can be optimized, the term "optimal" must be defined. In quantitative form, this is done by establishing a performance index (performance criterion, optimization criterion).

The optimization of a dynamic system means formulating the dynamic system behavior in an optimal way under the selected criterion. The system is characterized by the time-dependent processes by which it goes from a given initial state $x(t_0)$ to a final state $x(t_e)$.

The optimization of a controlled dynamic system generally begins with the system already specified; only the control scheme is varied to achieve the optimal system behavior. If the control structure is fixed, so that only its parameters can be varied, we speak of parametric op-

Figure 100. Magnitudes of the diagonal elements

Figure 101. Singular values of the sensitivity matrix and complementary sensitivity matrix

Figure 102. Magnitudes of the weight elements

Figure 103. Singular values of the sensitivity matrix and complementary sensitivity matrix

timization. For example, the Ziegler – Nichols rules (see Section 4.1) yield optimal controller parameters for PI or PID controllers and a class of systems. If, on the other hand, the control scheme – including its structure – can be freely chosen, this is referred to as structural optimization.

In the case of parametric optimization, the numerical values of the variable parameters are assigned a numerical rating based on the performance index; this rating is to be maximized or minimized through the variation and is thus a function of the parameters. In structural optimization, the entire time dependence of the control function $u(t)$ in the time interval $t_0 \leq t \leq t_e$ is varied. The performance index assigns a numerical rating to this function and is therefore a functional (quality functional, cost functional) [344].

Usually, the term "optimal control" is understood as referring to the results of a structural optimization, and this meaning will apply in the discussion that follows.

Optimization Problem. The starting point is a mathematical description of the system in state space (see Section 3.3) in the form of the system equation:

$$\dot{x}(t) = f(x(t), u(t), t) \tag{4.3.1}$$

What is now sought is the control function $u(t)$ that yields the minimum value of the performance index J for the process by which the system goes from the initial state $x(t_0) = x_0$ to a final state $x(t_e) = x_e$. This is the optimal control function $u*(t)$. Solving the system equation with given x_0 and $u*(t)$ gives the optimal state – space trajectory $x*(t)$ associated with $u*(t)$.

The final time t_e may be fixed or subject to choice, and similarly for the final state x_e or its components. Quantities that can be freely selected are available for variation; that is, they can be incorporated in the performance index.

Along with specifications of this kind, there are often constraints: State or control variables cannot, or must not, go outside certain value ranges at any time during the transition. For example, a value can be at most completely open or completely closed, the concentration of a species cannot take on values outside the range from zero to unity, and a reactor temperature must not go above a certain upper boundary or below a certain lower boundary.

The problem thus comprises

1) The system equation

2) The initial state x_0
3) The performance index J
4) Possible specifications of t_e and x_e
5) Possible constraints on x and u

Open- and Closed-Loop Optimal Control. For a given initial state x_0, the solution of the optimization problem yields an optimal control function $u*(t)$. It does not, however, say anything about how the control function can be technically implemented. There are two approaches to doing so:

In open-loop optimal control, the system state x is measured once at time t_0 and $u*(t)$ is determined from the result. For the remainder of the time interval $t_0 < t \leq t_e$, $u*(t)$ is presented at the control inputs of the system; no further account is taken of the system state. The control function is thus a function of time only from time t_0 onwards; it can be generated, for example, by a computer, which merely plays the role of a function generator.

Such an open-loop structure has, however, the disadvantage that the system follows the optimal trajectory $x*(t)$ only if no disturbances occur (see Section 4.1). For this reason, open-loop optimal control is often replaced by closed-loop optimal control. The optimal controller continuously generates the control function based on the current system state. If there are no disturbances, the controller holds the system on the optimal trajectory, thus behaving in the same way as the open-loop optimal controller. If disturbances occur, resulting in departures of the system from the optimal trajectory, the controller will initiate corrections so as to offset these departures while the transition process is still under way.

Performance Indices. A general form of performance index, which includes many special cases of importance in engineering [307], is the functional

$$J = h\left(x\left(t_e\right), t_e\right) + \int_{t_0}^{t_e} f_0\left(x\left(t\right), u\left(t\right), t\right) \mathrm{d}t \qquad (4.3.2)$$

The first term in this Bolza performance index evaluates the system behavior at the end of the transition process, while the integral term evaluates the entire process. This is known as a Mayer performance index if $f_0 = 0$, and as a Lagrange index for $h = 0$.

The following cases occur under the Lagrange performance index:

- $f_0 = u^{\mathrm{T}}(t)Mu(t)$, the energy-optimal performance index
- $f_0 = x^{\mathrm{T}}(t)Lx(t)$, the ISE performance index (performance index of the integral squared error type)
- $f_0 = 1$, the time-optimal performance index

The diagonal elements of the matrices M and L evaluate the squares of the control and state variables, respectively. All the other matrix elements are often simply set equal to zero.

Methods. This section lists the most important methods and concepts, with references to the literature.

The classical method of minimizing functionals is calculus of variations [307, 345, 346]. This technique is suitable for solving optimization problems without constraints on the control and state variables. An important special case, the closed-loop optimal control of linear systems [322, 323, 347] with quadratic performance index

$$J = x^T\left(t_e\right) Sx\left(t_e\right) + \int_{t_0}^{t_e} \left(x^T\left(t\right) Lx\left(t\right) + u^T\left(t\right) M\, u\left(t\right)\right) \mathrm{d}t$$

leads to the so-called Riccati controller.

Systems with constraints on the control variables can be optimized with the Pontryagin maximum principle [348–350]. Such constraints arise, in particular, in time-optimal control problems where the solution is expected to yield control functions that alternate between the upper and lower extreme values of the control variables. Feldbaum's theorem states, for a given class of systems, how many such alternations are required at a maximum.

Dynamic programming [351–353] is a general optimization method that can be used for, among other purposes, the optimization of dynamic systems. It offers the possibility of utilizing the constraints not only on the control variables but also on the state variables. An essential foundation of dynamic programming is Bellman's principle of optimality, which says that any final portion of an optimal trajectory is itself an optimal trajectory. This principle implies the basic procedure: The optimal trajectory and the associated open-loop optimal control scheme are determined in successive backward steps, beginning with the final state x_e.

A thematically organized literature survey of the optimization topics discussed here, as well as others, can be found in [307]; see also [354–359].

4.4. Binary Control

Principles. Classical control theory is concerned chiefly with "analog" signals, which are discrete as to time and value. The mathematical description of the process ("plant") and of the automation device ("controller") employs differential equations as well as transformations (Fourier, Laplace).

Industrial control practice, on the other hand, deals with all devices used to influence plants and machinery in a purposeful way. Traditionally, however, the emphasis is on working with binary signals (e.g., in relay and contactor controls) in open-loop structures [360]. Analog control loops occur only as low-level elements. Boolean algebra and its adaptation to hardware (switching algebra) are employed for the mathematical description of binary control [361].
